

How Debit Cards Enable the Poor to Save More

Pierre Bachas, Paul Gertler, Sean Higgins, and Enrique Seira*

October 24, 2018

Abstract

While formal savings can have a number of positive impacts for the poor, savings and active account use remain low. We study an at-scale natural experiment in Mexico in which debit cards are rolled out to beneficiaries of a cash transfer program, who already received transfers directly deposited into a savings account. Using administrative account data and household surveys, we find that after two years with a card, beneficiaries accumulate a savings stock equal to 2 percent of annual income. This effect size is larger than the impact of other interventions studied in the savings literature. We show that the increase in formal savings appears to be an increase in overall savings, financed by a voluntary reduction in current consumption. Debit cards increase account usage and savings through two mechanisms: first, they reduce the transaction costs of accessing money in the account; second, they reduce monitoring costs, which leads beneficiaries to check their account balances frequently and build trust in the bank. Camino a Santa Teresa 930, Mexico City 10700, enrique.seira@itam.mx. We are grateful to officials in Mexico's government bank Bansefi and the conditional cash transfer program Prospera (formerly Oportunidades) for sharing data and answering numerous questions. At Bansefi, we are indebted to Miguel Ángel Lara, Oscar Moreno, Ramón Sanchez, and especially Benjamín Chacón and Ana Lilia Urquieta. At Prospera, we are indebted to Martha Cuevas, Armando Gerónimo, Rodolfo Sánchez, Carla Vázquez, and especially Rogelio Grados, Raúl Pérez, and José Solís. For comments that greatly improved the paper, we thank David Atkin, Alan Barreca, Richard Blundell, Chris Carroll, Carlos Chiapa, Shawn Cole, Natalie Cox, Pascaline Dupas, John Edwards, Gerardo Escaroz, Fred Finan, Jess Goldberg, Emilio Gutierrez, Jens Hainmueller, Anders Jensen, Anne Karing, Dean Karlan, Supreet Kaur, Leora Klapper, David Laibson, Ethan Ligon, John Loeser, Nora Lustig, Jeremy Magruder, Justin McCrary, Atif Mian, Ted Miguel, Doug Nelson, Christine Parlour, Betty Sadoulet, Todd Schoellman, Ben Sperisen, Jonathan Zinman, and numerous seminar participants. We are also grateful to Ignacio Camacho, Ernesto Castillo, Oscar Cuellar, Bernardo García, Austin Farmer, Joel Ferguson, and Isaac Meza for research assistance. Gertler and Seira gratefully acknowledge funding from the Consortium on Financial Systems and Poverty and the Institute for Money, Technology & Financial Inclusion. Higgins gratefully acknowledges funding from the Fulbright–García Robles Public Policy Initiative and National Science Foundation (Grant Number 1530800). All authors declare that they have no relevant or material financial interests that relate to the research in this paper.

1 Introduction

A remarkably large number of households worldwide do not have sufficient savings to cope with relatively small shocks (Alderman, 1996; Dercon, 2002). For example, more than 40% of Americans report that they “either could not pay or would have to borrow or sell something” to finance a \$400 emergency (Federal Reserve, 2017). Some hypothesize that this is due to a lack of access to low-cost, convenient formal savings devices (Karlan, Ratan and Zinman, 2014). When the poor do save in formal financial institutions, there are a number of well-documented causal impacts including increased investment in agriculture, microenterprises, and children’s education, increased ability to cope with shocks, and reduced debt.¹ These positive impacts motivated Mullainathan and Shafir (2009, p. 126) to posit that access to formal financial services “may provide an important pathway out of poverty.”

Nevertheless, “uptake and active usage remain puzzlingly low” (Karlan et al., 2016, p. 2), even when accounts are offered without fees (Dupas et al., forthcoming). In fact, over 40% of adults worldwide do not have a formal bank or mobile money account (Demirgüç-Kunt et al., 2015). Similarly, cash transfer recipients paid through direct deposit into bank accounts generally withdraw the entire transfer amount in one lump sum each pay period (e.g., Aker et al., 2016; Muralidharan, Niehaus and Sukhtankar, 2016).

We study a natural experiment in which debit cards tied to existing savings accounts were rolled out geographically over time to beneficiaries of the Mexican conditional cash transfer program Oportunidades. Debit cards alleviate two important barriers to using formal financial institutions. First, debit cards lower the indirect transactions costs of accessing money in an account by facilitating more convenient access via a network of ATMs.² Second, debit cards also reduce the indirect cost of checking balances, which is a mechanism that individuals can use to monitor that banks are not unexpectedly reducing balances. Through monitoring, individuals build trust that money deposited in a bank account will be there when wanted. In fact, a lack of trust in banks to not “steal” their savings—often through hidden and unexpected fees—is frequently listed as a primary reason why the poor are hesitant to use banks (Dupas et al., 2016; FDIC, 2016). Among Oportunidades beneficiaries, “repeated balance checking is common, usually out of anxiety to confirm that their money is still there” (CGAP, 2012, p. 20).

The phased geographic rollout of debit cards to Oportunidades recipients provides plausibly exogenous variation in the timing of assignment of debit cards, allowing us to estimate the causal

¹See Dupas and Robinson (2013); Kast and Pomeranz (2014); Prina (2015); Brune et al. (2016).

²In our context, debit cards reduce the *indirect* time and transport transaction costs of accessing money in the bank account, as savings can be withdrawn at any bank’s ATM, rather than only at bank branches of a particular bank. In contrast, Schaner (2017) provides ATM cards that reduce *direct* transaction costs: higher withdrawal fees are charged by bank tellers in her study, and the only ATMs at which the cards can be used are located at bank branches of the corresponding bank.

impact of having a debit card on saving in a difference-in-differences event study framework. Before the rollout, beneficiaries had been receiving their transfers through savings accounts without debit cards, but rarely used their accounts to save: they typically withdrew the full transfer amount shortly after receiving it.³

Using high-frequency administrative data from nearly 350,000 beneficiary bank accounts in 359 bank branches nationwide over five years, we find that debit cards caused a large and significant increase in the active use of the accounts. The number of transactions (withdrawals) jumped immediately, while the proportion of beneficiaries holding significant positive savings in their bank account increased more slowly from 13% to 87% over a two-year period. After two years, beneficiaries with debit cards have built up a stock of savings equal to 2% of annual income. This increase in savings—caused by an at-scale and replicable intervention—is larger than that of most interventions in the literature, including commitment devices, no-fee accounts, higher interest rates, and financial education (Figure 1).⁴

Using a rich, high-quality household panel survey of a subsample of the beneficiaries, we then test whether the increase we observe in formal savings is an increase in *total* savings or a substitution from other forms of saving, both formal and informal. We focus on beneficiaries who have had the card for about a year at the time they are surveyed, and find that after one year with the card, there is no change in income and a significant reduction in consumption equal to about 4.9% of income. Because consumption and income are flows, and because the administrative bank account data show that the savings stock does not evolve linearly over time, we carefully compare the survey figure to the savings *rate* for beneficiaries from the same localities after they have had the card for the same amount of time as in the survey. The point estimates from the two sources of data are nearly identical (within 0.2% of income, or less than 50 cents per month) and each lies within the 95% confidence interval of the other.

This suggests that the total savings rate likely rose by a similar amount to what we observe in the administrative bank account data. As in most household surveys, however, our estimates are noisy: while we can reject that the increase in formal savings was purely substitution from other forms of savings, we cannot rule out that part of the increase in formal savings was substitution. More precisely, while our administrative data suggest a savings rate of 4.6% of income after one year with the card and the survey data point estimate is a reduction in consumption equal to 4.9% of income, the lower bound of the 95% confidence interval in the survey is 1.0% of income, while

³Prior to receiving cards, 13% of beneficiaries saved in the bank accounts. This is consistent with findings from other countries such as Brazil, Colombia, India, Niger, and South Africa, in which cash transfers are also paid through bank or mobile money accounts and recipients generally withdraw the entire transfer amount in one lump sum withdrawal each pay period (CGAP, 2012; Aker et al., 2016; Muralidharan, Niehaus and Sukhtankar, 2016).

⁴We also estimate a model of precautionary savings to estimate the equilibrium buffer stock, and find that beneficiaries are saving towards an equilibrium buffer stock of 2.7% of annual income. After saving in the account for one year, beneficiaries accumulate three-fourths of the equilibrium buffer stock on average.

the lower bound of the 90% confidence interval is 1.6% of income.

Why would debit cards lead to increased savings? An obvious candidate is that debit cards decrease the transaction costs of accessing money, which makes saving in the account more attractive since savings can be easily accessed when needed. Indeed, debit cards reduce the indirect transaction costs of accessing the account: before receiving a card, account holders had to go to one of only 500 Bansefi branches nationwide to withdraw money, traveling a median road distance of 4.8 kilometers.⁵ After receiving the card, each beneficiary could access her account at *any* bank's ATM, i.e. at any of the more than 27,000 ATMs in Mexico; the median road distance between a beneficiary's house and the closest ATM is 1.3 kilometers (Bachas et al., 2018). We find that the number of withdrawals made per month jumps by 40% immediately after receiving the card and stays relatively flat afterwards. Many beneficiaries start making two or three withdrawals per transfer period, while almost all beneficiaries used to make a single withdrawal of the entire transfer. Furthermore, 16% of beneficiaries begin accumulating savings immediately, likely due to the immediate reduction in transaction costs to access their money.

The reduction in transaction costs to access money does not by itself fully explain the increase in savings. The increase in savings is likely driven by a reduction in the transaction costs both of accessing money and of monitoring the bank. Upon receiving a debit card, most beneficiaries do not begin saving immediately, but instead appear to first use the card to monitor account balances and thereby build trust that their money is safe. Although a beneficiary could check her balance at Bansefi branches prior to receiving the card, the debit card makes it much more convenient since it allows balance checks at any bank's ATM.⁶ Thus, as in Labonne and Chase (2010), a reduction in transaction costs enables trust building. Once trust is established, beneficiaries take advantage of the reduced transaction costs associated with debit cards and increase the amount of savings held in their bank accounts.

Two main pieces of evidence support the mechanism of using the card to monitor balances and thereby build trust. First, using the high-frequency administrative data on bank account transactions, we observe that upon receipt of the debit card, clients initially leave small amounts of money in the account and use the card to check their account balances frequently, but reduce balance check frequency over time. Simultaneously, the proportion of beneficiaries who save in the account and the amount that they save rises over time with the card. We confirm this relationship statistically by testing for a negative *within*-account correlation between balance checks and savings; that is,

⁵This may explain their low initial use of the accounts to save, which in turn also explains why reduced transaction costs would not have the opposite effect of reducing savings. If clients were already already saving in their accounts and the transaction costs provided a form of commitment device, as was the case for one of the households profiled by Morduch and Schneider (2017), we might expect a reduction in transaction costs to reduce savings. However, most clients were not saving in the account prior to receiving a card.

⁶In addition, the reduced indirect transaction costs of accessing money in the account increase the potential benefit of saving formally, which would increase the beneficiary's desire to learn whether the bank is trustworthy.

people check their balances less at the same time that they save more, consistent with using balance checks to build trust.⁷ Second, in survey data from a subsample of the beneficiaries, those who have had their debit cards for a short period of time report significantly lower rates of trusting the bank than beneficiaries who have had their debit cards longer. We also rule out a number of alternative mechanisms including falling transaction costs over time and learning the banking technology, among others.

We thus make three main contributions to the literature. First, we show that debit cards caused a large and significant increase in the number of active account users in terms of both transactions and savings. The magnitude of the savings effect is larger than that of most other interventions studied in the literature. Comparing the stock of savings accumulated after 1–2 years in our study (relative to total annual household income) with estimates from other savings interventions—including offering commitment devices, no-fee accounts, higher interest rates, and financial education—we find that debit cards have a substantially larger effect (Figure 1). Two other studies that also find a large effect on savings are Suri and Jack (2016), who study the impact of mobile money, and Callen et al. (2014), who study the impact of weekly home visits by a deposit collector equipped with a point-of-sale terminal. Like debit cards, these technologies both lower transaction costs and enable clients to more easily monitor account balances.⁸

Second, we show that the savings effect comes—at least partially—from an increase in total savings achieved by reducing current consumption, rather than a substitution from other forms of saving. Other studies testing whether an increase in formal savings represents an increase in total savings or a substitution from informal savings generally do not have sufficient power to rule out full substitution, despite large point estimates on total savings (e.g., Ashraf, Karlan and Yin, 2015; Kast, Meier and Pomeranz, 2018).⁹ While account holders appear to reduce consumption as they increase savings over time in Somville and Vandewalle (2018, Figure 2), their consumption results are not statistically significant. In this paper, although we cannot rule out partial substitution, we definitively show that a portion (and based on the point estimates, possibly all) of the increase in formal savings is financed by reducing current consumption.

Third, we directly investigate two barriers to saving: indirect transaction costs and trust. We

⁷The Bansefi accounts do not charge overdraft fees, so this behavior is not consistent with checking balances to avoid overdraft fees when the account balance is low. Furthermore, the relationship holds—and becomes stronger—when we exclude balance checks that occur on the same day as a withdrawal, ruling out the possible explanation that beneficiaries check their balance before withdrawing only when they know they have a lower account balance.

⁸Mobile money clients can easily check account balances from their phones, and Callen et al.’s (2014) deposit collection includes a receipt printed in real-time with the deposit amount and new account balance after each weekly deposit—a feature that the bank viewed as crucial to establish trust in the deposit collectors. We were unable to include these studies in the comparison for reasons explained in Appendix A.

⁹An exception is Callen et al. (2014), who find a statistically significant impact on total savings that is similar in magnitude to the impact on formal savings. Unlike our paper, they find no impact on consumption but rather find that an increase in labor supply in response to the savings intervention enables the increase in savings.

find ample evidence that the immediate increase in the number of transactions is due to the decreased transaction costs of accessing the account, while the delayed increase in the proportion of beneficiaries who save is due to allowing clients to more easily monitor the bank by checking account balances, thereby increasing their trust in the bank over time. Studies have explored the role of trust in stock market participation, use of checks instead of cash, and mortgage refinancing in developed countries (Guiso, Sapienza and Zingales, 2004, 2008; Johnson, Meier and Toubia, forthcoming) and the role of trust in informal and formal borrowing and take-up of insurance products in developing countries (Karlan et al., 2009, 2015; Cole et al., 2013). There are few studies, however, that rigorously explore the role of trust as a constraint to saving or the role of financial technology in increasing trust (Karlan, Ratan and Zinman, 2014).¹⁰

In summary, debit cards combined with ATMs or point-of-sale terminals (and, in other contexts, mobile phones combined with mobile money platforms) are low-cost technologies that reduce the indirect transaction costs of both accessing funds in an account and checking balances to build trust in financial institutions. These technologies are simple, prevalent, and potentially scalable to millions of cash transfer recipients worldwide. Combining these technologies with government cash transfer programs could be a promising channel to increase financial inclusion and enable the poor to save, not only because of the sheer number of people that are served by cash transfers, but also because many governments and nongovernmental organizations are already embarking on digitizing their cash transfer payments through bank or mobile money accounts (e.g., Aker et al., 2016; Muralidharan, Niehaus and Sukhtankar, 2016).

2 Institutional Context

We examine the rollout of debit cards to urban beneficiaries of Mexico’s conditional cash transfer program Oportunidades, whose cash benefits were already being deposited directly into formal savings accounts without debit cards. Oportunidades is one of the largest and most well-known conditional cash transfer programs worldwide, with a history of rigorous impact evaluation (Parker and Todd, 2017). The program provides cash transfers to poor families conditional on sending their children to school and having preventive health check-ups. It began in rural Mexico in 1997 under the name Progresa, and later expanded to urban areas starting in 2002. Today, nearly one-fourth of Mexican households receive benefits from Oportunidades, recently rebranded as Prospera.

As it expanded to urban areas in 2002–2005, Oportunidades opened savings accounts in banks for beneficiaries in a portion of urban localities, and began depositing the transfers directly into

¹⁰Previous studies on debit cards and mobile money have focused on the effect of the lower transaction costs facilitated by these technologies to make purchases, access savings and remittances, and transfer money (Zinman, 2009; Jack and Suri, 2014; Schaner, 2017), but not their capacity to monitor and build trust in financial institutions. Two studies on trust and savings are Osili and Paulson (2014), who study the impact of past banking crises on immigrants’ use of banks in the US, and Mehrotra, Vandewalle and Somville (2016), who promote interactions with bankers and find that account savings is strongly associated with trust in one’s own banker.

those accounts. By 2005, beneficiary families in over half of Mexico's urban localities were receiving their transfer benefits directly deposited into savings accounts in Bansefi, a government bank created to increase savings and financial inclusion among underserved populations. The Bansefi savings accounts have no minimum balance requirement or monthly fees and pay essentially no interest.¹¹ No debit or ATM cards were associated with the accounts, so beneficiaries could only access their money at Bansefi bank branches. Because there are only about 500 Bansefi branches nationwide and many beneficiaries live far from their nearest branch, accessing their accounts involved large transaction costs. Overall, the savings accounts were barely used prior to the introduction of debit cards: 89.9% of clients made one withdrawal each bimester, withdrawing 99.5% of the transfer on average (Table B.1).¹²

In 2009, the government began issuing Visa debit cards to beneficiaries who were receiving their benefits directly deposited into Bansefi savings accounts. The cards enable account holders to withdraw cash and to check account balances at any bank's ATM, as well as make electronic payments at any store accepting Visa. Beneficiaries can make two free ATM withdrawals per bimester at any bank's ATM; additional ATM withdrawals are charged a fee that varies by bank. When Bansefi distributed the debit cards, they also provided beneficiaries with a training session on how and where to use the cards (Appendix C). The training sessions did not vary over time and did not discuss savings, nor encourage recipients to save.

Our sample consists of urban beneficiaries who received their transfer benefits in bank accounts prior to the rollout of debit cards. As shown in Figure 2, beginning in January 2009 debit cards tied to these existing bank accounts were rolled out to beneficiaries by locality. When Bansefi distributed cards in a particular locality, all beneficiaries in that locality received cards during the same payment period. By the end of 2009, about 75,000 beneficiaries had received debit cards tied to their pre-existing savings accounts. Another 172,000 beneficiaries received cards by late 2010. By October 2011, the last month for which we have administrative data from Bansefi, a total of 256,000 beneficiaries had received debit cards tied to their pre-existing savings accounts. Another 93,000 beneficiaries received cards between November 2011 and April 2012, shortly after the end date of our study period. We use this last group as a "pure" control group throughout the duration of our study, although as we describe in Section 4, we take advantage of all the variation in exposure time generated by the staggered rollout of cards over time. The map in Figure 2b shows that the card expansion had substantial national geographic breadth throughout the rollout.

The introduction of debit cards to existing recipients was not randomized, but we test whether—

¹¹Nominal interest rates were between 0.09 and 0.16% per year compared to an inflation rate of around 5% per year during our sample period.

¹²A bimester is a two-month period; Oportunidades payments are paid every two months. Our measure of percent withdrawn can exceed 100% of the transfer since the account could have a positive balance prior to the Oportunidades payment.

among urban localities included in the rollout—the timing determining when cards were rolled out to various localities is correlated with observable locality-level characteristics. To test this, we follow Galiani, Gertler and Schargrotsky (2005) and Gertler et al. (2016) and use a discrete time hazard model, which is equivalent to testing whether in a given period t , the probability of being treated at t conditional on not being treated yet at $t - 1$ is correlated with observables. We include measures of the pre-treatment levels and trends of financial infrastructure, as well as all of the locality-level variables used by Mexico’s National Council of Social Development Policy Evaluation—the independent government agency that produces Mexico’s official poverty estimates—to determine locality-level development gaps. We reject that the timing of the rollout is correlated with observables among localities included in the rollout: of the 20 variables included in the model, the coefficient on one variable is statistically significant at the 5% level (as would be expected by chance), and the remaining coefficients are statistically insignificant (Table 2).¹³

3 Data Sources

We use four main sources of data. The first is administrative data on account balances and transactions from Bansefi on the universe of beneficiaries who already received benefits in a savings account and were then awarded a debit card. We also use three surveys of Oportunidades beneficiaries. Table 1 displays the number of beneficiaries, time periods, main variables, and variation we exploit for each of these data sources.

3.1 Administrative Data

To examine the effect of debit cards on savings and account use, we exploit account-level balance and transactions data from Bansefi for the universe of accounts that received transfers in a savings account prior to receiving a debit card. These data consist of 348,802 accounts at 359 Bansefi branches over almost five years, from January 2007 to October 2011. They include monthly average savings balance; the date, amount, and type of each transaction made in the account (including Oportunidades transfers); the date the account was opened, and the month the card was given to the account holder. Figure 2a shows the timing of the administrative data and the rollout of debit cards.

Table B.1 shows summary statistics from this dataset. Using data from the first bimester of 2008 (before any debit cards were disbursed to beneficiaries), the accounts in our sample make 0.01 client deposits and 1.1 withdrawals per bimester on average, and the average amount withdrawn is 99.5% of the Oportunidades transfer, indicating very low use of the account for saving prior to receiving the card. Net balances are 124 pesos or about US\$11 on average; the distribution of net balances is skewed: the 25th percentile is just 2 pesos (US\$0.2) and the median is 42 pesos (US\$4).

¹³In addition to these 20 variables, we include a 5th-order polynomial in time, as in Galiani, Gertler and Schargrotsky (2005).

The average amount transferred by Oportunidades in the first bimester of 2008 is 1,540 pesos, or about US\$144, per bimester; using survey data we find that Oportunidades income represents about one-fourth of beneficiaries' total income on average. The average account had already been open for 3.5 years by January 2008, so beneficiaries in our study had substantial experience with a savings account prior to receiving the debit card.

3.2 Survey data

Since its inception in 1997, Oportunidades has a long history of collecting high-quality surveys from their beneficiaries, and these surveys have been used extensively by researchers (Parker and Todd, 2017). We use three distinct Oportunidades household-level surveys, described below. Figures B.1–B.3 show when survey respondents received cards in each of these surveys, relative to the timing of the survey.

3.2.1 Household Panel Survey (ENCELURB)

The most comprehensive survey data we use is the Encuesta de las Características de los Hogares Urbanos (ENCELURB), a household panel survey with comprehensive modules on consumption, income, and assets. The survey includes three pre-treatment waves in 2002, 2003, and 2004, and one post-treatment wave conducted between November 2009 and February 2010. The surveys were originally collected for the evaluation of the program in urban areas. Localities that switched to debit cards in early 2009 were oversampled in the fourth wave (which did not return to all localities from the original sample for budgetary reasons). As a result, most of the treatment group in this survey—beneficiaries who received cards prior to the fourth wave of the survey—had the card for close to one year when surveyed. We exclude the group of beneficiary households in this survey that received cards in late 2009, shortly before the post-treatment survey wave; these households would not have had the card long enough to begin saving.¹⁴ We merge the survey with administrative data from Oportunidades on the debit card expansion to study the effect of the card on consumption and saving in a difference-in-differences model.

3.2.2 Trust Survey (ENCASDU)

The Encuesta de Características Sociodemográficas de los Hogares Urbanos (ENCASDU), conducted in 2010, is a stratified random sample of 9,931 Oportunidades beneficiaries. We refer to this survey as the Trust Survey since it gives us our main measure of trust in the bank. We restrict our analysis to beneficiaries who had already received debit cards by the time of the survey, since the module with questions we use about reasons for not saving was only asked to those who had already received debit cards. This leaves us with a sample of 1,694 households, with a median

¹⁴Because only 74 of the 2942 households in this survey living in urban localities included in the rollout are in localities treated in late 2009, our results hardly change if we do not drop these households. We drop them for cleaner comparisons with the administrative data results.

exposure to the card of 14 months.

Our main trust measure comes from this survey. The survey asks, “Do you leave part of the monetary support from Oportunidades in your bank account?” If the response is no, the respondent is then asked the open-ended question, “Why don’t you keep part of the monetary support from Oportunidades in your Bansefi savings account?” *Lack of trust* is captured by responses such as “because if I do not take out all of the money I can lose what remains in the bank”; “because I don’t feel that the money is safe in the bank”; “distrust”; and “because I don’t have much trust in leaving it.”¹⁵ We also merge this survey with administrative account data to relate savings and reported trust measures directly.

3.2.3 Payment Methods Survey

The Encuesta de Medios de Pago (Payment Methods Survey) is a cross-sectional survey of a stratified random sample of 5,388 beneficiaries, conducted in 2012. This survey was fielded to measure operational details of the payment method. In particular, it asks about use of the debit cards and beneficiaries’ experiences using ATMs. We use it to measure the self-reported number of balance checks and withdrawals with the card, whether beneficiaries get help using an ATM, and if they know their card’s PIN by heart. We restrict the analysis to the 1,617 surveyed beneficiaries who responded to the relevant module of the survey from the sampled urban localities that received cards; median exposure time to the card is 12 months.

4 Empirical Strategy and Identification

We exploit variation generated by the staggered rollout of debit cards to different localities by Oportunidades. When the data has a panel dimension—i.e., the administrative data and the Household Panel Survey—we estimate a difference-in-differences specification. When we only have a cross-section of cardholders—i.e., the Trust Survey and Payment Methods Survey—we exploit variation in the length of time beneficiaries have been exposed to the card. In both cases the underlying variation we use stems from the exogenous rollout of debit cards over time. In this section, we present the main empirical models we use and verify the plausibility of the identification assumptions needed for a causal interpretation.

4.1 Generalized Difference-in-Differences (Event Study)

The large sample over a long period of time in the administrative data allows us to estimate a generalized difference-in-differences specification where the treatment effect is allowed to vary dynamically over time and is measured in “event time” relative to each beneficiary’s treatment date. In other words, we use an event study specification with a pure control group throughout the

¹⁵We also use this question to define alternative reasons for not saving, including *lack of knowledge* (e.g., “they didn’t explain the process for saving”) and *fear of ineligibility* (e.g., “because if I save in that account they can remove me from the Oportunidades program”).

study period. Specifically, we estimate

$$y_{it} = \lambda_i + \delta_t + \sum_{k=a}^b \phi_k D_{it}^k + \varepsilon_{it} \quad (1)$$

where y_{it} is the outcome of interest, i and t index account and period respectively, the λ_i are account-level fixed effects, and the δ_t are calendar-time fixed effects. D_{it}^k is a dummy variable indicating that account i has had a debit card for exactly k periods at time t , while $a < 0 < b$ are periods relative to the switch to debit cards; we measure effects relative to the period before getting the card, so we omit the dummy for $k = -1$. For those in the control group who receive cards after our study period ends, $D_{it}^k = 0$ for all k .¹⁶ We use this specification to study withdrawals and savings in the account. We average time over four-month periods since payments are sometimes shifted to the end of the previous bimester.¹⁷ We estimate cluster-robust standard errors, clustering ε_{it} by Bansefi branch.

As in any difference-in-differences model, to interpret each ϕ_k as the causal effect of having the card for k periods, we need to invoke a parallel trend assumption: in the absence of the card, early and late recipients would have had the same account use and savings behavior. While this is untestable, we test for parallel pre-intervention trends by showing that $\phi_k = 0$ for all $k < 0$ whenever we use specification 1. Figures 5–7 show parallel pre-treatment trends in the number of withdrawals, stock of savings, and savings rate. Parallel pre-treatment trends also hold for client deposits, which are zero in virtually all accounts.

4.2 Difference-in-Differences with Survey Data

With the household survey panel data, we estimate a standard difference-in-differences model since we observe just one time period after treatment. We estimate

$$y_{it} = \lambda_i + \delta_t + \gamma D_{j(i)t} + v_{it}, \quad (2)$$

where y_{it} is consumption, income, or the stock of assets for household i at time t . Time-invariant differences in household observables and unobservables are captured by the household fixed effects λ_i , common time shocks are captured by the time fixed effects δ_t , and $D_{j(i)t} = 1$ if locality j in which beneficiary household i lived prior to treatment has received debit cards by time t . We use

¹⁶Since we have a control group that does not receive cards until after the study period ends (as in McCrary, 2007), we can pin down the calendar-time fixed effects without facing the under-identification problems described in Borusyak and Jaravel (2016). We set a and b as the largest number of periods before or after receiving the card that are possible in our data, but only graph the coefficients representing three years before receiving the card and two years after (see Borusyak and Jaravel, 2016, on why this is better than “binning” periods below some \underline{k} or above \bar{k}).

¹⁷This could cause an artificially large end-of-bimester balance if the recipient had not yet withdrawn their transfer. Payment shifting happens for various reasons, including local, state, and federal elections, as a law prohibits Oportunidades from distributing cash transfers during election months.

the locality of residence prior to treatment to avoid confounding migration effects, and estimate cluster-robust standard errors clustered by locality.

The identifying assumption is again parallel trends. We verify parallel pre-treatment trends by estimating $y_{it} = \lambda_i + \delta_t + \sum_k \omega_k T_{j(i)} \times \mathbb{I}(k = t) + \eta_{it}$, where k indexes survey round ($k = 2002$ is the reference period and is thus omitted), $T_{j(i)} = 1$ if locality j in which beneficiary i lives is a locality that received cards before the post-treatment survey wave, and $\mathbb{I}(k = t)$ are time dummies. Thus, the ω_k for $k < 2009$ estimate placebo difference-in-differences effects for the pre-treatment years. For each variable, we fail to reject the null of parallel trends using an F-test of $\omega_k = 0$ for all $k < 2009$ (Table 3b, column 4).

4.3 Cross-Section Exploiting Variation in Time with Card

The Trust Survey and Payment Methods Survey are cross-sections of beneficiaries with cards (hence there is no pure control group), and each survey has less than 2,000 observations. This poses constraints: we have to rely on exposure time to the card as the identifying variation, and to economize on power, we split the beneficiaries into two equal-sized groups based on how long they have had the card. Concretely, we regress the outcome variable—such as self-reported trust—on a dummy of whether beneficiary i 's exposure to the card is below median exposure:

$$y_i = \alpha + \gamma \mathbb{I}(\text{Card} \leq \text{median time})_i + u_i, \quad (3)$$

where u_i is clustered at the locality level.

This specification requires orthogonality between the error term u_i and timing of card receipt for a causal interpretation of γ —a stronger identification assumption than parallel trends.¹⁸ We thus conduct balance tests using (3) with characteristics that should not be affected by debit card receipt as the dependent variable, such as number of household members, age, gender, status, and education level, as well as variables unaffected by debit card receipt in the Household Panel Survey, such as assets and income. Table 3b shows that in our survey samples, those with the card for less and more than the median time are balanced, consistent with our finding that the timing of treatment of localities included in the rollout was not correlated with observables.¹⁹

It is worth emphasizing that the beneficiaries in the household surveys are a strict subset of the beneficiaries in the administrative data, and that the underlying variation in all specifications stems from exposure time to the card, which was determined exogenously by Oportunidades' rollout of

¹⁸An additional issue with this specification is that, to the extent that treatment has immediate effects, we may be biased against finding an effect since all our observations here are treated.

¹⁹In the Trust Survey, outcomes are balanced for 9 out of 10 variables; 1 of 10 variables has a statistically significant difference at the 10% significance level, as would be expected by chance. The Payment Methods Survey includes fewer measures of household characteristics since the survey was focused on experience with the debit cards and ATMs. We find no statistically significant differences in the 5 variables on household characteristics included in the Payment Methods Survey.

debit cards.

5 Effect of Debit Cards on Account Use and Savings

In this section, we use the administrative data from Bansefi on all transactions and average monthly balances in 348,802 accounts of Oportunidades beneficiaries to estimate the dynamic effect of debit cards on the use of accounts (deposits and withdrawals), stock of savings in these accounts, and savings rate. To interpret the results, we first note that beneficiaries begin using their debit cards to make withdrawals at ATMs almost immediately (rather than continue to make withdrawals at bank branches). In the four-month period in which they receive cards, 85% of beneficiaries withdraw money from an ATM, and this increases to over 90% in subsequent periods (Figure 3).

5.1 Transactions

By lowering indirect transaction costs, debit cards should lead to more transactions, as predicted by theory (Baumol, 1952; Tobin, 1956) and empirical evidence (Attanasio, Guiso and Jappelli, 2002; Schaner, 2017). This is indeed what we find. Figure 4a shows the distribution of the number of withdrawals per bimester, before and after receiving the card. Prior to receiving the card, 90% of beneficiaries made a single withdrawal per bimester. The distribution of withdrawals in the control group is nearly identical to that of the treatment group prior to receiving a debit card. In contrast, after receiving the card, 67% of beneficiaries continue to make just one withdrawal, but 25% make 2 withdrawals, 5% make 3 withdrawals, and 2% make 4 or more withdrawals.²⁰ Although the debit cards can be used at any store that accepts card payments, the majority of transactions on the card are made at ATMs: including card purchases in the definition of withdrawals, 11% of the total withdrawn and 22% of withdrawals are made at stores. Meanwhile, the number of withdrawals in the control group does not change over time (Figure B.4).

On the other hand, there is no effect on client deposits: Figure 4b shows that 99% of accounts have zero client deposits per bimester before and after receiving the card. Account holders thus do not add savings from other sources of income to their Bansefi accounts. This finding is not surprising, since beneficiaries receive about one-fourth of their total income from the Oportunidades program on average, so unless the optimal savings rate in a particular period is higher than 25% of total income, there is no reason to deposit more into the savings account from other income sources.

In order to examine the evolution of the debit card's effect on withdrawals over time, we estimate the generalized difference-in-differences or event study specification from (1), with withdrawals per bimester as the dependent variable. Figure 5 plots the ϕ_k coefficients of average with-

²⁰After receiving the card, store purchases can also be made on the debit card; these are grouped together with withdrawals. Recall that the first two withdrawals per bimester are free at any bank's ATM, but subsequent withdrawals are charged a fee, which may explain why few beneficiaries make more than two withdrawals even after receiving the card.

drawals per bimester for each four-month period, compared to the period just before receiving cards. Prior to receiving the card, pre-trends are indistinguishable between treatment and control: we cannot reject the null of $\phi_k = 0$ for all $k < 0$. In addition to having parallel trends, both treatment and control accounts average just under one withdrawal per period on average. The effect on withdrawals is *immediate*, as would be expected from the instantaneous change in transaction costs induced by the card. Prior to receiving the card, beneficiaries in both the treatment and control groups average about 1 withdrawal per bimester, but immediately after receiving the card, treated beneficiaries begin making an additional 0.4 withdrawals per bimester on average.

5.2 The Stock of Savings (Account Balances)

Next, we explore whether debit cards cause an increase in savings from period to period. The increased number of withdrawals shown in Section 5.1 will lead to a mechanically higher average balance *within* each period, but this does not necessarily mean beneficiaries are accumulating saving in the account over time, i.e., *across* periods. They could just be leaving some money in the account after the first withdrawal in the pay period, but withdrawing the remaining money later in the same period thereby leaving the account balance close to zero by the end of that period.

Since we are interested in a measure of saving across periods but do not observe end-of-period balance, we adjust the average balance measure to remove the mechanical effect resulting from making more (lower-amount) withdrawals after receiving the card. Using the timing and amount of each transaction, we calculate and subtract off the mechanical effect for each account-bimester observation to obtain a measure of “net balance” to study period-to-period savings (see Appendix D for more details).²¹

We estimate (1) with account i ’s net balance in period t as the dependent variable.²² The ϕ_k terms thus measure the causal effect of debit cards on the stock of savings k periods after receiving a card. Figure 6 plots the ϕ_k coefficients and their 95% confidence intervals. First, note the parallel trends for $k < 0$.²³ In the first few periods after receiving a card, there is a small savings effect of about 100 pesos (about US\$8). The initial effect is small because only some beneficiaries begin saving shortly after receiving a card—we explore this further below. Savings increase substantially after about one year with the card: three periods after card receipt, the savings effect is 448 pesos, while it is 753 pesos after two years with the card. These effect sizes are equal to 1.2 and 2.0% of annual income, respectively, and are larger than the effect sizes found in other studies of savings

²¹We use this measure rather than forcing initial balance in January 2007 to zero and constructing end-of-period balance using the transactions data since the average balance data reveal that a small portion of beneficiaries do save in their accounts prior to 2007, as we discuss in Section 5.3.

²²Following other papers measuring savings (e.g., Kast, Meier and Pomeranz, 2018), we winsorize savings balances at the 95th percentile to avoid results driven by outliers.

²³In 8 of the 9 pre-treatment periods, there is no statistically significant difference between the savings balance of the treatment and control groups.

interventions (Figure 1).

The effect of debit cards on the average stock of savings from Figure 6 combines two effects: the impact of debit cards on the probability of saving and savings conditional on saving. Figure 7a shows the first component, i.e. the proportion of treated beneficiaries who save each period. While just 13% of beneficiaries saved in their account in the period before receiving cards, Figure 7a shows that an additional 16% of beneficiaries start saving immediately after receiving a card. For these beneficiaries, it is likely that the reduction in the transaction costs of accessing savings provided by the cards was a sufficient condition to save in a formal bank account. The proportion of beneficiaries who save in their Bansefi accounts increases over time: after nearly one year with the card, 42% of beneficiaries save in the account, and after two years nearly all beneficiaries (87%) save in their Bansefi account.

To estimate the second component, i.e. the amount of savings conditional on having started to save, we define a new event as the period in which a beneficiary begins saving (rather than when the beneficiary receives a card). Although this event is endogenous, we merely want to descriptively observe the amount of savings each period after having started to save—an event that occurs at different points in time for different beneficiaries, due to both the timing of receiving cards and the timing of when they begin saving after receiving a card. We estimate (1) using this new event. Because no individuals save prior to our new event of starting to save, we impose a zero pre-trend (i.e., we impose $\phi_{k^*} = 0$ for all $k^* < 0$, where k^* is used to denote periods relative to starting to save). The results are shown in Figure 7b.²⁴ In the first period that they save in the account, beneficiaries deposit about 589 pesos on average, or 4.7% of their total income that period. They deposit significantly less in the following periods, consistent with models of precautionary saving in which an individual’s savings rate is decreasing in her stock of savings as it approaches her buffer stock target (Carroll, 1997).

5.3 Equilibrium Buffer Stock

Since many beneficiaries are still accumulating savings after two years with the card, we do not have sufficient time periods to *directly* measure their equilibrium buffer stock. To estimate the buffer stock that they are saving toward, we add a bit of structure motivated by models of precautionary saving. The precautionary savings motive (Deaton, 1991) leads to a savings target, and as a result, an individual’s savings rate is decreasing in her stock of savings as it approaches the target (Carroll, 1997). Hence, we model the flow of savings in a particular period, denoted $\Delta Savings_{it} \equiv Savings_{it} - Savings_{i,t-1}$ (where $Savings_{it}$ is beneficiary i ’s stock of savings in period t), as a function of the stock of savings in the previous period and income in the current period. Implementing this as a linear model and including time-period fixed effects, we have

²⁴Because the majority do not begin saving until they have had the card for a year, we only graph the savings stock for three post-saving periods (as further-period estimates would be based solely on the small sample of earlier savers).

$\Delta Savings_{it} = \delta_t + \theta Savings_{i,t-1} + \gamma Income_{it} + \varepsilon_{it}$.²⁵ Models of precautionary saving predict that $\theta < 0$, since the amount of new savings decreases as the stock of savings approaches the target level.

We are not actually able to implement the above model as specified because we are restricted to using bank account information rather than data on overall savings and income. Instead, we estimate the *change in net account balances* (rather than change in total savings) as a function of lagged *net balances* (instead of lagged total savings) and *transfers deposited during the period* (instead of total income). Despite lacking data on total savings and total income, under a set of testable assumptions we can interpret the results as corresponding to the equilibrium buffer stock of overall savings. Specifically, we need to assume that (i) there are no deposits into the account other than the transfer, (ii) having a debit card does not affect other sources of income, and (iii) having a debit card does not affect other non-account savings. The first two assumptions imply that the debit card can only affect savings out of transfers and not through other sources of income, enabling us to use transfer income rather than total income. The third assumption, which we provide evidence for in Section 6, implies that any increase in savings in the bank account does not substitute for other forms of saving, so that an increase in bank savings constitutes an increase in total savings.

Because we are interested in the equilibrium buffer stock savers are building towards once they begin saving, we only include those who have started saving at some point during the study period (87% of treated beneficiaries) and the pure control group in our estimation, and again define a new event as the period in which a beneficiary begins saving. In order to identify the effects of the debit card on the savings rate over time, we interact the terms from the above model with these time-since-saving event dummies. Thus, we estimate

$$\begin{aligned} \Delta Savings_{it} = & \delta_t + \sum_{k^*=0}^b \alpha_{k^*} D_{it}^{k^*} + \theta Savings_{i,t-1} + \sum_{k^*=0}^b \xi_k D_{it}^{k^*} \times Savings_{i,t-1} \\ & + \gamma Transfers_{it} + \sum_{k^*=0}^b \psi_k D_{it}^{k^*} \times Transfers_{it} + \varepsilon_{it}, \end{aligned} \quad (4)$$

where k^* again denotes periods relative to starting to save. We do not include pre-trends (i.e., we estimate coefficients from $k^* = 0$ to b rather than from $k^* = a < 0$ to b) because lagged net balances are zero prior to starting to save, so the ξ_{k^*} parameters for $k^* < 0$ are unidentified.

We then estimate the savings rate k^* periods after starting to save as

$$\hat{\Phi}_{k^*} \equiv (\hat{\alpha}_{k^*} + \hat{\xi}_{k^*} \omega_{k^*-1} + \hat{\psi}_{k^*} \mu_{k^*}) / \bar{Y}, \quad (5)$$

²⁵We do not include individual fixed effects, since including individual fixed effects and a lagged dependent variable would bias our estimates (Nickell, 1981).

where ω_{k^*-1} is average lagged net balance and μ_{k^*} is average transfers k^* periods after starting to save; \bar{Y} is average income.²⁶ The numerator in (5) gives the difference between treatment and control in the flow of savings in pesos; the denominator divides by average income to obtain the savings rate.²⁷ We use the delta method to estimate standard errors and thereby construct confidence intervals.

Figure 8 shows that the period after beginning to save, the average beneficiary saves 4.3% of income, and this falls over time (to a savings rate of 3.4% of income after one year of saving) as her stock of savings approaches her target.²⁸ Models of precautionary saving predict that the savings rate should fall once a positive savings balance is achieved, with the savings rate dampened by a negative coefficient on lagged balance. We indeed find $\theta = -0.58 < 0$ (with a cluster-robust standard error of 0.02) and $\theta + \xi_{k^*} < 0$ for all k^* .

To estimate the equilibrium buffer stock, we note that once a beneficiary has reached her equilibrium buffer stock, $Savings_{it} = Savings_{i,t-1}$; we plug this into (4) to solve for equilibrium savings for those with a card and obtain $Savings = (\alpha + \psi \cdot Transfers)/(-\xi)$. Using averages for these coefficients from periods after beneficiaries begin saving, we predict that the average equilibrium buffer stock is 1008 pesos (US\$78); to put this quantity in context, it equals 2.7% of beneficiaries' annual income. After one year of saving in the account (and up to two years with the card), the beneficiaries who save—who make up over 80% of beneficiaries—have accumulated 76% of their desired buffer stock on average.

6 Increase in Overall Savings vs. Substitution

The increase in formal savings in beneficiaries' Bansefi accounts might represent a shift from other forms of saving, such as saving under the mattress or in informal saving clubs, with no change in overall savings. This section investigates whether the observed increase in Bansefi account savings crowds out other savings. We take advantage of Oportunidades' Household Panel Survey, conducted in four waves during the years 2002, 2003, 2004 and November 2009 to February 2010.

We use a simple difference-in-differences identification strategy where we examine changes in beneficiaries' consumption, income, and stock of assets, again exploiting the differential timing of debit card receipt. We compare trends of those with cards at the time of the fourth survey wave to those who had not yet received cards. Section 4 formally tested for parallel pre-treatment trends for each dependent variable and failed to reject the null hypothesis of parallel trends. Nevertheless, because there is a lot of variation in household-level pre-trends and the point estimates on the pre-

²⁶Results are robust to excluding the $Transfer_{it}$ interaction terms; see Figure B.5. Because transfer amounts vary for a number of reasons (described in Appendix E), we control for them in the preferred specification.

²⁷Average income is obtained from the 2009–10 wave of the Household Panel Survey (described in Section 3). It is scaled to a four-month period to match the time period of the estimated effect of the debit card on the flow of savings.

²⁸As in Section 5.2, we only graph the savings rate conditional on saving for three post-saving periods (as further-period estimates would be based solely on the small sample of earlier savers).

trends tend to be noisy, in our preferred specification we control for interactions between time fixed effects baseline household characteristics, including household-level pre-trends (as in de Janvry et al., 2015).²⁹ We estimate (2)—with the additional interaction of time fixed effects and baseline household characteristics in our preferred specification—separately for three dependent variables: consumption, income, and an asset index.³⁰

Table 4, column 4 shows that consumption decreased by about 154 pesos per month among treated households relative to control (statistically significant at the 5% level). We do not find any effect on income. We also test the difference in the coefficients of consumption and income using a stacked regression (which is equivalent to seemingly unrelated regression when the same regressors are used in each equation, as is the case here); although both consumption and income are noisily measured, the difference in the coefficients is significant at the 5 or 10% level in all specifications (the p-value of the F-test of equality of the coefficients on consumption and income is 0.062 in column 4). Table 4 columns 1–3 show that our results are robust to the extent of winsorizing and to removing the controls for flexible time trends as a function of household characteristics and pre-trends. The stock of assets does not change, ruling out a crowding out of this form of saving.

These point estimates suggest that the increase in formal savings shown in Section 5 represents an increase in total savings. To compare estimates from the survey and administrative data, we first note that the survey estimate on consumption—which equals 4.9% of monthly income—is measured as a flow. Furthermore, it is a flow at a specific point in time relative to receiving the cards (which matters given our finding from the administrative data that the savings stock does not evolve linearly over time): since we excluded those who were treated shortly before the survey wave, the survey estimate corresponds to the effect of cards on consumption after approximately one year with the card.

To compare this to the *flow* of savings after one year with the card for a comparable set of beneficiaries in the administrative data, we restrict the administrative data to the same set of treatment localities from the survey that are treated about one year before the post-treatment survey wave. We then take the average $\Delta Savings_{it}$ from the administrative data for accounts from this set of localities and for the particular period t after exactly one year with the card (where the Δ is computed relative to the preceding four-month period, as usual). We divide this flow of savings in pesos after one year with the card from the administrative data by average income over a four-month period, which is taken from the survey. This gives us an estimate from the administrative data of the effect of debit cards on the flow of savings of 4.6% of income, which is within 0.2% of income—or less than 50 cents per month—of the survey estimate. Furthermore, each of the two estimates (i.e., from

²⁹We also show results for the difference-in-differences specification without these controls; the point estimates do not change substantially.

³⁰Standard errors shown in parentheses are cluster-robust asymptotic standard errors, clustered at the locality level. There are 46 localities. We also show wild cluster bootstrap percentile- t 95% confidence intervals in square brackets.

administrative data and the survey) is within the 95% confidence interval of the other estimate.

As in most household surveys, however, our estimates are noisy: while we can reject that the increase in formal savings was purely substitution from other forms of savings, we cannot rule out that some but not all of the increase in formal savings was substitution. Using the confidence intervals estimated using a percentile- t wild cluster bootstrap, the lower bound of the 95% confidence interval for our estimate is a reduction in consumption equal to 33 pesos per month or 1.0% of income; the lower bound of the 90% confidence interval is 50 pesos per month or 1.6% of income.

We also use the survey data to test whether the increase in formal savings observed in the administrative bank account data crowds out a particular form of informal saving: investment in durable assets. We test whether beneficiary households are disinvesting in assets by using a measure of the stock of assets (an asset index). We find that the difference-in-differences coefficients on this measure are small and statistically insignificant. This suggests that, at least in the first year after receiving a card, beneficiaries are not substituting informal savings in assets to formal savings in the bank. Nevertheless, it does not rule out that they might intend to spend their account savings on durable assets in the future, such that we might see an effect on assets if we had survey data over a longer time horizon.

7 Mechanisms

The card decreases indirect transaction costs to both access savings and monitor account balances. In this section we provide evidence that both mechanisms were at work in causing the increased active use of the accounts and the large increase in savings. We also explore several other mechanisms such as learning the ATM technology.

7.1 Transaction Costs to Access Account

Consistent with economic theory on the effect of an immediate decrease in transaction costs (Baumol, 1952; Tobin, 1956), we observe an immediate increase in the number of withdrawals per period (Figure 5). The percentage of clients who use their debit card to make at least one withdrawal at an ATM or convenience store instead of going to the bank branch also increases immediately after receiving the card—to about 85% of beneficiaries—and then is fairly stable in subsequent periods (Figure 3). We also observe that 16% of beneficiaries were not saving prior to receiving a debit card and begin saving immediately after receiving the card, likely due to the change in transaction costs (Figure 7a).

The immediate decrease in transaction costs provided by debit cards cannot, however, explain the gradual increase over time in the proportion of beneficiaries who save in their Bansefi accounts after receiving cards (Figure 7a). The only way transaction costs could *solely* explain the increase in savings caused by debit cards—and in particular the gradual increase over time with the card in the proportion of beneficiaries who save—would be if transaction costs were also gradually

changing over time. This, however, would be inconsistent with the immediate increase and then relatively flat time profile of both the proportion of beneficiaries who withdraw their benefits at ATMs (Figure 3) and the number of withdrawals per period (Figure 5).

In addition, there is substantial direct evidence that changing transaction costs over time cannot explain the gradual increase in the proportion who save. First, we test and reject that banks disproportionately expanded complementary infrastructure (e.g., the number of ATMs) in treated localities, which would further decrease the transaction cost of accessing funds in a way that is geographically correlated with the debit card expansion. We use data on the number of ATMs and bank branches by municipality by quarter from the Comisión Nacional Bancaria y de Valores (CNBV), from the last quarter of 2008—the first quarter with available data—through the last quarter of 2011. We estimate a difference-in-differences specification with six leads and lags, $y_{mt} = \lambda_m + \delta_t + \sum_{k=-6}^6 \beta_k D_{m,t+k} + \varepsilon_{mt}$, where y_{mt} is the number of total ATMs, total bank branches, Bansefi ATMs, or Bansefi branches in municipality m in quarter t , and D_{mt} equals one if at least one locality in municipality m has Oportunidades debit cards in quarter t . We conduct an F-test of whether lags of debit card receipt predict banking infrastructure (i.e., whether there is a supply-side response to the rollout of debit cards: $\beta_{-6} = \dots = \beta_{-1} = 0$), and an F-test of whether leads of debit card receipt predict banking infrastructure (i.e., whether debit cards were first rolled out in municipalities with a recent expansion of banking infrastructure: $\beta_1 = \dots = \beta_6 = 0$). We find evidence of neither relationship (Table B.2).

Second, we test whether the increase in the proportion of savers over time with the card could be explained by a concurrent increase in the number of ATMs across all localities. Only beneficiaries in treatment localities can access money at ATMs and hence take advantage of an expansion of ATMs. If the gradual increase in the proportion saving over time is due to a gradual decrease in transaction costs that is uncorrelated with the geographical expansion of debit cards, we would also expect savings to increase among Bansefi debit card holders who are not Oportunidades beneficiaries. We look at mean savings among non-Oportunidades debit card account holders who opened their accounts in 2007 and hence have had the account for about two years when our study period begins. Figure B.6 shows that savings among non-Oportunidades debit card holders do not increase over the study time period, and instead stay relatively flat. This suggests that the increase over time in the proportion who save cannot be explained by a gradual decrease in transaction costs over time.

Third, beneficiaries' *perceptions* of transaction costs might change even if transaction costs remain constant over time with the card. For example, perhaps they are checking balances to learn about direct transaction costs (i.e., fees), in which case they would check balances less frequently once transaction costs are learned. We directly test and reject this hypothesis using the Payment Methods Survey, which asks beneficiaries how much the bank charges them for (i) a balance check

and (ii) a withdrawal after the initial free withdrawals. We find that beneficiaries get the level of these fees about right and, more important, that there is no difference across beneficiaries who have had the card for less vs. more than the median time (Figure B.7a).

In sum, the debit cards lead to an immediate change in transaction costs to access savings, which causes an immediate increase in the number of withdrawals per period and an immediate increase in the proportion who save. However, the proportion who save continues to increase over a two-year period, and this effect cannot be explained solely by transaction costs.

7.2 Monitoring Costs and Trust

Trust in financial institutions is low worldwide (Figure B.8) and is positively associated with saving in formal bank accounts (Figure B.9). Furthermore, a lack of trust in banks is frequently cited by the poor as a primary reason for not saving (Dupas et al., 2016; FDIC, 2016). The time delay between receiving the debit card and starting to save (for most beneficiaries) is consistent with the hypothesis that the debit card reduces the indirect cost of checking account balances, leading to an increase in balance checks to monitor that the bank is not regularly reducing beneficiaries' account balances. Although a beneficiary could check her balance at Bansefi branches prior to receiving the card, the debit card makes it much more convenient since it allows balance checks at any bank's ATM. The median household lives 4.8 kilometers (using the shortest road distance) from the nearest Bansefi branch, compared to 1.3 kilometers from an ATM (Bachas et al., 2018).

Under this hypothesis, each additional balance check provides additional information about the bank's trustworthiness. With simple Bayesian learning, balance checks have a decreasing marginal benefit as a beneficiary updates her beliefs about the bank's trustworthiness, which would lead to a decrease in the number of balance checks over time. Hence, over time with the card, we expect the number of balance checks to fall and trust to rise.

We test this mechanism in three steps. We first show that balance checks fall over time in both administrative and survey data. Second, we examine whether higher savings balances are negatively correlated with the number of balance checks *within* accounts in the administrative data, as they should be if beneficiaries begin saving once they've used the card to monitor the bank and build trust through balance checks. Third, we use survey data to test whether self-reported trust in the bank increases over time with the card.

7.2.1 Balance Checks Fall Over Time with the Debit Card

We first use the Bansefi transactions data to test whether balance checks fall over time with the card. We only observe balance checks once beneficiaries have debit cards, which restricts our analysis to the treatment group and to periods after the card is received.³¹ On average, beneficiaries check

³¹We do not observe balance checks at Bansefi branches in the transaction data since these are not charged a fee. However, it is unlikely that many beneficiaries used this mechanism to monitor the bank prior to receiving a card due

their balances 1.9 times per four-month period after receiving cards. To test the hypothesis of a decreasing time trend in balance checking, we regress the number of balance checks on account fixed effects and event-time dummies (omitting the last period with the card): $Balance\ Checks_{it} = \lambda_i + \sum_{k=0}^{\bar{k}_i-1} \pi_k D_{it}^k + \varepsilon_{it}$.³² The π_k coefficients graph the number of balance checks k periods after receiving the card relative to the last period in the sample (July–October 2011), which depending on the beneficiary corresponds to one to two years after receipt of the card.

Figure 9a plots the π_k coefficients using any balance check to construct the dependent variable, and shows that the number of balance checks in the periods following receipt of the debit card is higher than in later periods. For example, in the period after receiving the card, beneficiaries make 1.03 more balance checks compared to two years after receiving the card. After having the card for about one year, this falls to about 0.4 more checks.

For learning to occur, beneficiaries need a positive balance in their account at the time of checking. We find that in the four months after getting the card, 89% of accounts have a positive (small) balance at the time of a balance check after receipt of the transfer: the 25th percentile of balances at the time of a balance check is 20 pesos, the median is 55 pesos, and the 75th percentile is 110 pesos.³³

To ensure that a balance check constitutes bank monitoring and not just checking that the Oportunidades deposit arrived, we additionally use two alternative, more restrictive definitions of a balance check.³⁴ The first alternative definition excludes all balance checks that occurred *prior* to the transfer being deposited that bimester, and also excludes balance checks that occur on the same day as a withdrawal. The idea is that if a beneficiary is checking whether the transfer has arrived, and she finds that it has, she would likely withdraw it that same day. An even more conservative definition only includes balance checks that occur after that bimester’s transfer has arrived *and the client has already withdrawn part of the transfer*. Because the next transfer would not arrive until the following bimester and the beneficiary has already made a withdrawal in the current bimester, the beneficiary knows that the current bimester’s transfer has arrived. Hence, these checks cannot be an attempt to see if the transfer has arrived. Figures 9b and 9c plot the results with these two alternative definitions and show a very similar decrease in balance checks over time.

We validate the above results using survey data from the Payment Methods Survey. Specifi-

to the high costs of traveling to the nearest Bansefi branch.

³² \bar{k}_i denotes the last period with the card for account i in our data, which varies depending on when i received a card. We do not include time fixed effects since we can only include treated beneficiaries after treatment in the regression, and the within-account trend in balance checks over time (among this group) is precisely the variation we are exploiting. ε_{it} are clustered at the bank branch level.

³³For these statistics, we take the conservative approach of defining a balance as positive if the cumulative transfer amount minus the cumulative withdrawal amount in the bimester is positive at the time of the balance check (this is a sufficient but not necessary condition for the balance to be positive).

³⁴Note that beneficiaries were given calendars with exact transfer dates and hence should know the dates on which transfers are deposited; see Figure C.3. Figure B.10 illustrates the three definitions of balance checks that we use.

cally, we estimate (3) using the self-reported number of balance checks over the past bimester as the dependent variable. Figure 9d shows that those who have had the card for more than the median time (12 months) make 31% fewer trips to the ATM to check their balances without withdrawing money than those who have had the card for less time. The self-reported survey responses thus confirm the findings from the administrative data, and also show that balance checking behavior is salient for beneficiaries.

7.2.2 Negative Correlation between Balance Checks and Savings Balances

Our hypothesis—that monitoring balances leads to increased trust which leads to increased savings—predicts that there will be a negative correlation between balance checks and savings *within* accounts. To test this, we estimate $Savings_{it} = \lambda_i + \sum_{c \neq 0} \eta_c \mathbb{I}(Checks_{it} = c) + \varepsilon_{it}$, where $Savings_{it}$ is the net balance in account i at time t , the λ_i are account-level (i.e., beneficiary) fixed effects, and $Checks_{it}$ is the number of balance checks in account i over period t , which we top code at 5 to avoid having many dummies for categories of high numbers of balance checks with few observations.³⁵ The η_c coefficients thus measure the within-account correlation between the stock of savings and number of balance checks, relative to the omitted zero balance checks ($c = 0$) category. Our hypothesis suggests that $\eta_c < 0$, and that η_c is decreasing (i.e., becoming more negative) in c .

Figure 10 shows the results. Account balances are indeed negatively correlated with the number of balance checks within accounts. Using any of the three definitions of balance checks described earlier, η_c is less than 0 and decreasing in c . Furthermore, the negative correlation between savings and balance checks is stronger when we restrict the definition of balance checks to those that we argued earlier are more likely to be the type of checks used to monitor the bank. Using balance checks that occur only after the beneficiary has already made a withdrawal in the same bimester (panel c), we find that beneficiaries who make one balance check save 300 pesos less than those who make no balance checks, while beneficiaries who make 3 or more balance checks save nearly 500 pesos less.

7.2.3 Trust Increases over Time with the Debit Card

We now test the hypothesis that longer tenure with the debit card induces higher trust in the bank. As described in Section 3.2, the Trust Survey first asks the beneficiary if she saves in her Bansefi bank account, and if she answers no, it asks why not. If she does not save in the account and indicates that she does not trust the bank, we code *lack of trust* as 1; otherwise (including if the beneficiary saves in the account) we code lack of trust as 0.

We estimate (3) with lack of trust as the dependent variable, again exploiting the exogenous

³⁵We do not include time fixed effects since we can only include treated beneficiaries after treatment in the regression, and the within-account changes in the stock of savings over time (among this group) is precisely the variation we are exploiting. ε_{it} are clustered at the bank branch level.

variation in the length of time beneficiaries have had the card. As explained in Section 4, to interpret γ in (3) as a causal effect we need to assume that time with the card is orthogonal to our potential outcomes of interest. The balance tests conducted for the Trust Survey sample support this assumption (Table 3a), as does the finding that conditional on being included in the debit card rollout, the timing of when cards were distributed to the locality is uncorrelated with observables (Table 2). Figure 11 shows that trust increases over time: beneficiaries with more than the median time with the card are 33% less likely to report not saving due to low trust.³⁶ For comparison, Figure 11 also shows results for two alternative forms of learning discussed in Sections 7.3.1 and 7.3.2: learning to use the technology and learning that the program will not drop beneficiaries who accumulate savings. Few beneficiaries report these as reasons for not saving, and the proportion does not change over time with the card.

7.3 Learning

Monitoring the bank and building trust is one type of learning; in this section we explore evidence that other types of learning are occurring. We do not find evidence of these other types of learning.

7.3.1 Learning the Technology

The time delay for many beneficiaries between getting the card and saving suggests some type of learning. Building trust is one form of learning. Here we explore an alternative type of learning: learning how to use the technology. This type of learning would have to occur gradually over time to explain our results. However, in addition to the survey evidence against this form of learning that we present below, learning the technology is inconsistent with the result from the administrative data that the number of withdrawals and use of ATMs increase *immediately* after receiving the card and remain fairly stable over time afterwards.

Beneficiaries could be learning how to use their debit cards over time. The Payment Methods Survey asks each respondent whether (i) it is hard to use the ATM, (ii) she gets help using the ATM, and (iii) she knows her PIN by heart. We use these three questions as dependent variables in (3). Figure B.7b shows that there is no statistically significant difference between the group who have had the card for less vs. more than the median time. Beneficiaries could instead be learning how to save in the account (rather than how to use the card). This is unlikely as these beneficiaries have already had the account for years prior to receiving a debit card. Consistent with this, less than 2% respondents to the Trust Survey cite not saving due to lack of knowledge.³⁷ Moreover,

³⁶Note that because of the timing of the Trust Survey, those with the card for less than the median time have still had the card for at least 9 months, meaning that some of them would have likely developed trust in the bank prior to being surveyed. Those with more than the median time with the card have had it for 5 months longer on average. If anything, this may bias our results downward relative to what we would find if it were possible to compare those who have a sufficient tenure with the card to those who have not yet received the card.

³⁷Examples of responses coded as lack of knowledge are “I don’t know how to use the card so I withdraw everything at once” and “I don’t know how [to save in the account].”

there is no difference between those who have had the card for less vs. more than the median time (Figure 11).

7.3.2 Learning the Program Rules

Beneficiaries may have initially thought that saving in the account would make them ineligible for the program, but learned over time that this was not the case. In the Trust Survey, there are some responses along these lines such as “because if I save in the account, they can drop me from Oportunidades.” We thus estimate (3) with the dependent variable equal to 1 if respondents do not save for this reason. Less than 4% of beneficiaries do not save due to fear of being dropped from the program, and the proportion does not change when comparing those who have had the card for less vs. more than the median time (Figure 11).

7.3.3 Time with the Bank Account

Experience with the savings account rather than time with the debit card itself cannot explain the delayed savings effect. First, savings accounts were rolled out between 2002 and 2005, and therefore beneficiaries had several years of experience with the account when debit cards were first introduced in 2009. Second, both treatment and control accounts are accumulating time with their savings accounts simultaneously, and have had accounts for the same amount of time on average. Third, our results from Section 5 include account fixed effects, so any time-invariant effect of having the account for a longer period of time would be absorbed.

8 Conclusion

Debit cards tied to savings accounts could be a promising avenue to facilitate formal savings, as debit cards reduce transaction costs and provide a mechanism to check balances and build trust in financial institutions. We find large effects of debit cards on savings. The debit cards were rolled out over time to beneficiaries of Mexico’s cash transfer program Oportunidades, who were already receiving their benefits in a bank account, but who—for the most part—were not saving in their accounts. After two years with a debit card, beneficiaries increase their stock of savings by 2% of annual income. Extrapolating our estimates from a precautionary savings model to future periods, we predict that beneficiaries are saving towards an equilibrium buffer stock of 2.7% of annual income. The effect we find is larger than that of various other savings interventions, including offering commitment devices, no-fee accounts, higher interest rates, lower transaction costs, and financial education. Furthermore, this effect arises in an at-scale policy change affecting hundreds of thousands of cash transfer beneficiaries across the country.

Both trust in banks and low transaction costs to access savings appear to be necessary but not (individually) sufficient conditions to save in formal financial institutions. While cross-country and qualitative evidence had shown that transaction costs and low trust in banks might be barriers

to saving, we provide evidence that a causal relationship exists: we combine high-frequency administrative bank transactions and survey data with an empirical design that exploits a staggered, plausibly exogenous rollout of debit cards. High indirect transaction costs and low trust could potentially explain why a number of studies offering the poor savings accounts with no fees or minimum balance requirements have found low take-up and, even among adopters, low use of the accounts.

While we are not able to directly assess the welfare implications of this policy, a growing literature suggests that enabling the poor to save in formal accounts leads to increased welfare through greater investment and ability to cope with shocks, leading to higher long-term consumption. It is worth noting that beneficiaries with the debit card voluntarily use the technology and build savings in their accounts (whereas they could continue withdrawing all of their benefits from the bank branch, as they did prior to receiving the card); this indicates a revealed preference for saving in formal financial institutions once transaction costs are lowered and trust is built. Furthermore, beneficiary survey responses in the Trust Survey indicate that satisfaction with the payment method is higher after receiving the debit card, particularly for those who have had the card longer: 75% of beneficiaries who have had the card for at least 14 months (the median time) indicate that receiving payment by debit card is better than before.³⁸

Taken together, these results suggest that combining debit cards or mobile banking with government cash transfer programs could be a promising channel to increase financial inclusion and enable the poor to save.

Notes: $N = 240$ localities in the debit card rollout, and 1851 locality by two-month-period observations in columns 3 and 4. Columns 1 and 2 show summary statistics of locality-level financial infrastructure, trends in financial infrastructure, and other locality characteristics. Columns 3 and 4 test whether these characteristics predict the timing of when localities receive debit cards as part of the debit card rollout, using a discrete time hazard model. Column 3 shows results from a linear probability discrete time hazard model, as in Gertler et al. (2016). Column 4 shows results from a discrete proportional hazard using a complementary log-log regression. Both models also include a 5th-order polynomial in time as in Galiani, Gertler and Schargrodsky (2005); time is measured in two-month periods. The dependent variable in the discrete time hazard model is a dummy variable indicating if locality j has been treated at time t . A locality treated in period t drops out of the sample in period $t + 1$ since it is a hazard model. All variables are measured prior to the debit card rollout. The financial variables come from various sources, and are each measured in the last day or quarter of 2008 (just prior to the debit card rollout); pre-rollout trends (variables with a Δ) compare the last day or quarter of 2006 to the last day or quarter of 2008. The number of point-of-sale (POS) terminals is from Mexico's Central Bank and includes POS terminals from all merchant categories; checking accounts, commercial bank branches, and commercial bank ATMs are from CNBV; Bansefi bank branches are from a data set of Bansefi branch geocoordinates. We do not include trends in Bansefi bank branches or commercial bank ATMs because these variables are first available in 2008. The non-financial locality characteristics include all characteristics that are used to measure locality-level development by Mexico's national statistical institute (INEGI) and its National Council for the Evaluation of Social Development (CONEVAL), and come from publicly available locality-level totals from the 2005 Population Census published by INEGI.

Table 3: Balance and Parallel Trends in Survey Data

Panel (a): Cross-Sectional Data	Trust Survey			Payment Methods Survey		
	(1) α (Mean for card > median time)	(2) γ (Difference card \leq median time)	(3) P-value of difference	(4) α (Mean for card > median time)	(5) γ (Difference card \leq median time)	(6) P-value of difference
# Household members	5.18 (0.08)	0.26 (0.15)	0.114	4.78 (0.07)	-0.04 (0.13)	0.767

Male	0.67 (0.03)	0.02 (0.03)	0.603	0.03 (0.01)	0.00 (0.01)	0.874
Married	0.70 (0.04)	0.02 (0.03)	0.459	0.73 (0.02)	-0.01 (0.03)	0.867
Education level	9.30 (0.16)	-0.33 (0.18)	0.092	6.01 (0.20)	0.03 (0.29)	0.910
# Children	2.19 (0.08)	0.03 (0.10)	0.743			
Occupants per room	3.50 (0.07)	-0.03 (0.11)	0.801			
Health insurance	0.59 (0.02)	0.05 (0.03)	0.165			
Asset index	0.04 (0.04)	-0.04 (0.08)	0.605			
Income	3193.93 (47.53)	222.55 (147.11)	0.151			
Panel (b): Panel Data	Household Panel Survey					
	(1) Control Mean	(2) ω_k (Placebo DD) 2003	(3) 2004	(4) Parallel p-value		
Consumption	2725.87 (78.54)	2.61 (80.88)	9.74 (85.11)	0.949		
Income	3150.82 (88.37)	263.20 (218.88)	273.82 (224.00)	0.476		
Asset Index	0.50 (0.09)	-0.03 (0.05)	-0.02 (0.05)	0.672		

Notes: This table tests for balance between those who have had a debit card for more vs. less than the median time in the two cross-sectional surveys, and for parallel trends in the panel survey. Panel (a) shows results from $y_i = \alpha + \gamma \mathbb{I}(\text{Card} \leq \text{median time})_i + u_i$: column 1 shows the mean for those with a card for more than the median time (α), column 2 the difference in means for those with the card less than the median time (relative to those with the card more than the median time; γ), and column 3 reports the p-values for a test of $\gamma = 0$. In the Trust Survey, individual sociodemographic characteristics refer to those of the household head (but the program beneficiary responded to the trust questions). The Payment Methods Survey was a more focused survey that included fewer sociodemographic questions, which is why some rows are blank in the columns corresponding to that survey; individual sociodemographic characteristics are those of the program beneficiary. $N = 1,694$ beneficiary households for the Trust Survey and 1,617 for the Payment Methods Survey. Panel (b) shows the control mean and a parallel trend test for each of the outcome variables used in the household panel survey. The parallel trends test is from $y_{it} = \lambda_i + \delta_t + \sum_k \omega_k T_{j(i)} \times \mathbb{I}(k = t) + \eta_{it}$, where k indexes survey waves; we additionally include household baseline characteristic by time fixed effects as in our preferred specification in Table 4. The “Placebo DD” columns (where DD = difference-in-differences) show ω_{2003} and ω_{2004} ($k = 2002$ is the omitted reference period), while the “Parallel p-value” column is from an F-test of $\omega_{2003} = \omega_{2004} = 0$. $N = 7,754$ household-period observations from 2,200 households in the Household Panel Survey as in column 4 of Table 4.

Table 4: Effect of Debit Cards from Household Panel Survey

	(1)	(2)	(3)	(4)
Consumption	-175.36** (81.31) [-353.11, -1.52]	-150.51** (70.43) [-306.24, -2.30]	-136.52** (61.75) [-276.37, -4.75]	-154.80** (62.04) [-288.09, -33.00]
Income	98.16 (170.03) [-290.77, 486.11]	106.01 (150.31) [-230.64, 468.97]	75.50 (127.77) [-219.75, 376.72]	38.59 (106.02) [-172.05, 251.23]
Asset index	0.06 (0.08) [-0.12, 0.24]	0.06 (0.08) [-0.12, 0.24]	0.07 (0.07) [-0.08, 0.23]	0.03 (0.08) [-0.20, 0.24]
P-value Consumption vs. Income	[0.047]	[0.041]	[0.056]	[0.062]
Number of households	2,868	2,868	2,868	2,200
Number of observations	9,246	9,246	9,246	7,754
Time fixed effects	Yes	Yes	Yes	Yes
Household fixed effects	Yes	Yes	Yes	Yes
Household characteristics \times time	No	No	No	Yes
Winsorized	No	1%	5%	5%

Notes: This table shows the effect of the debit cards on consumption, income, and assets using the Household Panel Survey combined with administrative data from Oportunidades on the debit card rollout. Each row label is the dependent variable from a separate regression; each column is a different specification. Means for each dependent variable can be found in Table 3b. Asymptotic cluster-robust standard errors (clustered at the locality level, using pre-treatment locality) are included in parentheses; wild cluster bootstrap percentile- t 95% confidence intervals are included in square brackets. Dependent variables are measured in pesos per month, with the exception of the asset index. Asset index is the first principal component of assets that are included in both the early (2002, 2003, 2004) and post-treatment (2009–2010) versions of the survey: car, truck, motorcycle, television, video or DVD player, radio or stereo, washer, gas stove, and refrigerator. For column 4, household characteristics are measured at baseline (2004, or for households that were not included in the 2004 wave, 2003). They include characteristics of the household head (working status, a quadratic polynomial in years of schooling, and a quadratic polynomial in age), whether anyone in the household has a bank account, a number of characteristics used by the Mexican government to target social programs (the proportion of household members with access to health insurance, the proportion age 15 and older that are illiterate, the proportion ages 6-14 that do not attend school, the proportion 15 and older with incomplete primary education, the proportion ages 15-29 with less than 9 years of schooling), dwelling characteristics (dirt floors, no bathroom, no piped water, no sewage, and number of occupants per room), and pre-trends in the four dependent variables (consumption, income, purchase of durables, and asset index). The number of households in column (4) is lower because households have missing values for one of the household characteristics included, or are not included in enough pre-treatment waves to construct household-level pre-trends of the outcome variables, which are interacted with time fixed effects in that specification.

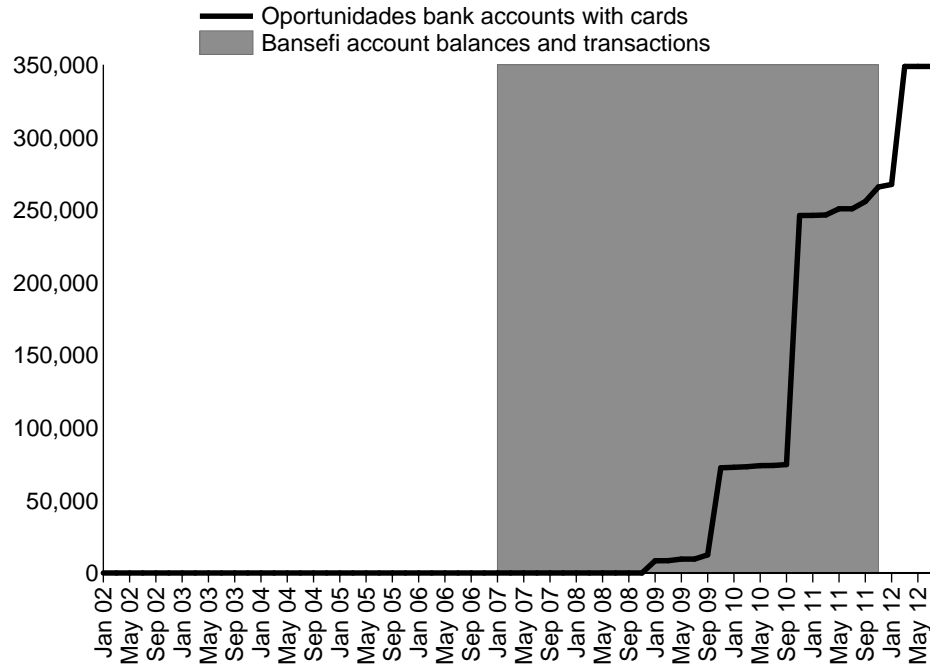

Figure 1: Comparison with Other Studies

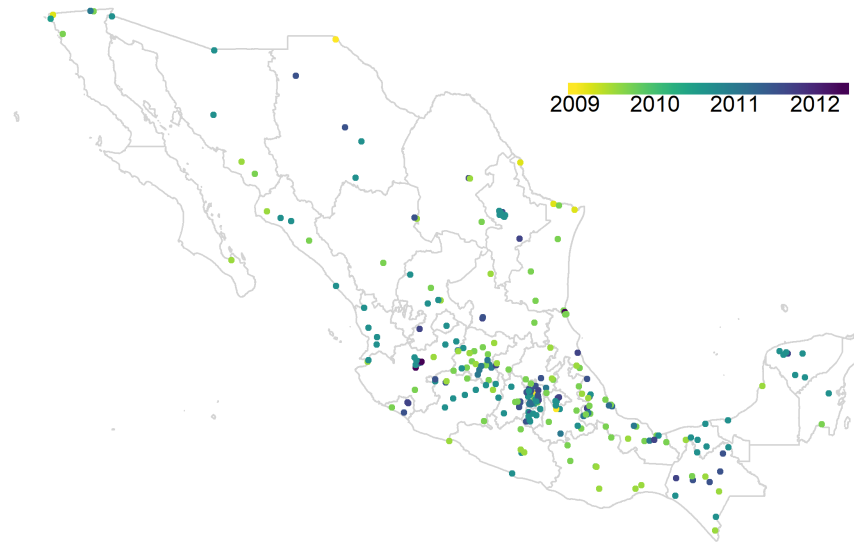

Notes: This figure compares the results from our study after 1 and 2 years with a debit card (orange squares) to other studies of savings interventions, and shows that we find larger effects than most studies with a comparable duration. Panel (a) shows studies with about a 1 year duration and panel (b) studies with a longer duration. The effect sizes are intent-to-treat effects of the intervention on the stock of savings, measured as a proportion of annual income. Appendix A details the selection criteria to determine which studies could be included and how we obtained their effects on the stock of savings as a proportion of annual income. Whiskers denote 95% confidence intervals. Black circles indicate results that are significant at the 5% level, gray circles at the 10% level, and hollow circles statistically insignificant from 0.

Figure 2: Debit Card Rollout over Time and Space

(a) Timing of Rollout and Administrative Data

(b) Geographic Coverage

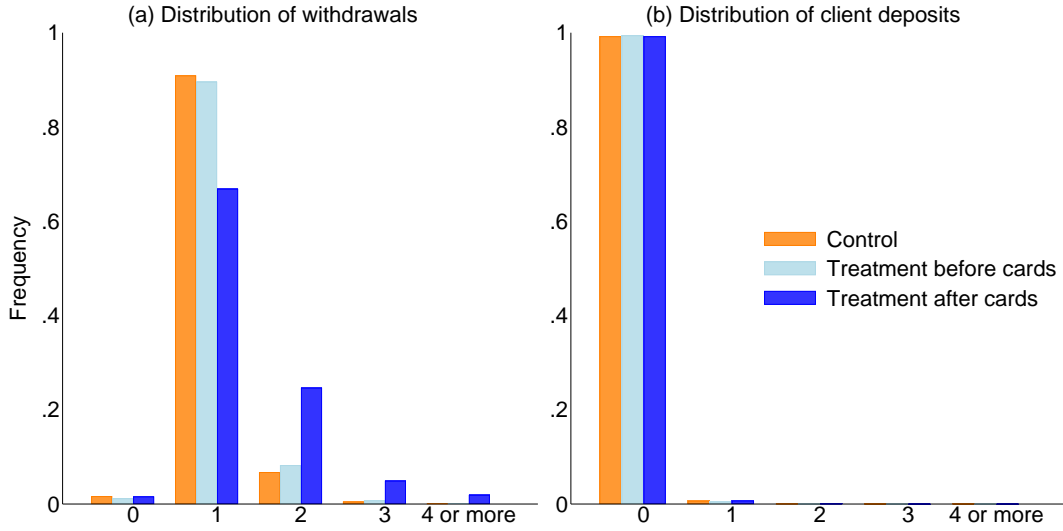

Notes: This figure shows the number of Oportunidades bank accounts with debit cards over time (using administrative data from Bansefi) and across space (using administrative data from Oportunidades). This was determined by the staggered rollout of debit cards, which generated variation across space and time in having a debit card tied to the bank account in which beneficiaries receive their benefits. Panel (a) compares the timing of the rollout to the timing of the administrative bank account data and panel (b) shows the rollout across space.

Figure 3: Share of Clients Using Debit Cards to Withdraw at ATMs

Notes: This figure shows the share of clients using their debit card for at least one withdrawal during a four month period. It shows that beneficiaries immediately adopt the new technology and use their cards to withdraw their transfers, instead of going to the Bansefi bank branch. Note that in periods before the card the share of clients using debit cards to withdraw at ATMs or convenience stores is necessarily zero. $N = 3,362,690$ account-period observations from 250,792 *treated* beneficiaries. Standard errors are clustered at the bank branch level. Whiskers denote 95% confidence intervals. Dashed vertical line indicates timing of debit card receipt.

Figure 4: Distribution of Withdrawals and Client Deposits per Bimester

Notes: This figure shows the distribution of withdrawals per bimester in panel (a) and of client deposits per bimester (i.e., excluding Oportunidades deposits) in panel (b). The three categories represent accounts in the control group, the treatment group before receiving the cards and the treatment group after receiving the card. Within each group, all account-bimester observations are included. It shows that after receiving a card, a substantial portion of beneficiaries began making 2, 3, or 4 or more withdrawals per bimester rather than one. Based on all transactions from 348,802 beneficiaries over 5 years.

Figure 5: Effect of Debit Cards on Number of Withdrawals per Bimester

Notes: This figure shows the effect of the debit card on the number of withdrawals per bimester. It plots the ϕ_k coefficients from equation (1), where the dependent variable is number of withdrawals. $N = 4,740,331$ account-period observations from 348,802 beneficiaries. Standard errors are clustered at the bank branch level. Whiskers denote 95% confidence intervals. Black circles indicate results that are significant at the 5% level, and hollow circles statistically insignificant from 0.

Figure 6: Effect of Debit Cards on the Stock of Savings (Pesos)

Notes: This figure shows the effect of debit cards on the stock of savings and the proportion who save. Dashed vertical lines indicate timing of debit card receipt. It plots the ϕ_k coefficients from equation (1), where the dependent variable is net savings balance. $N = 4,664,772$ account-period observations from 348,802 beneficiaries. Whiskers denote 95% confidence intervals. Black circles indicate results that are significant at the 5% level, and hollow circles statistically insignificant from 0.

Figure 7: Decomposition of Savings Effect

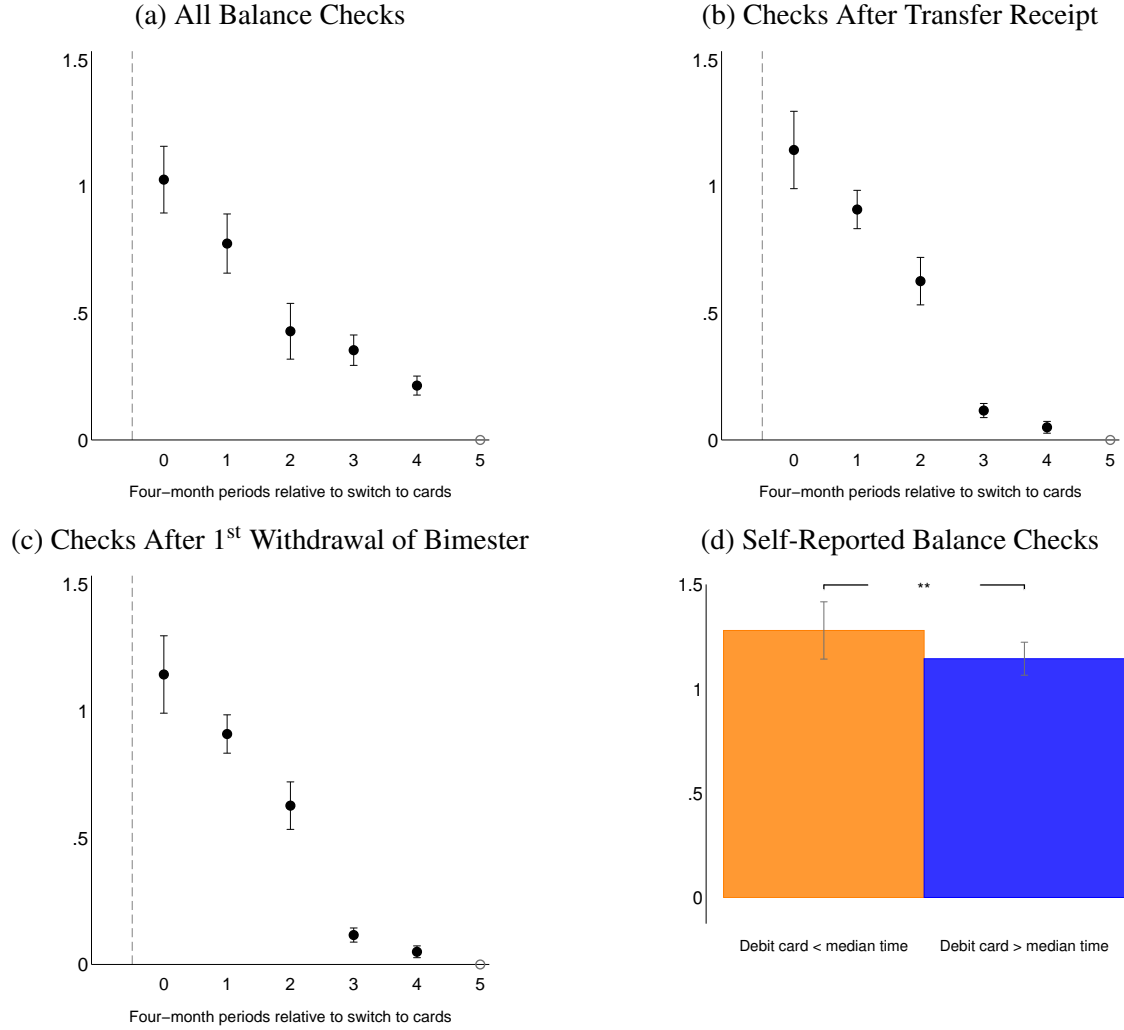

Notes: This figure decomposes the effect of the debit card on the stock of savings into the extensive margin effect on the proportion who save over time, and the intensive margin effect on the stock of savings conditional on saving. Panel (a) shows the proportion of treated beneficiaries who save in each period relative to when they receive a debit card. $N = 3,183,050$ account-period observations for 255,784 *treated* beneficiaries. Panel (b) plots ϕ_k from (1) with the event time dummies redefined relative to when an individual starts saving in the account, and we impose a zero pre-treatment trend by setting $a = 0$ (for reasons explained in Section 5.3). $N = 4,416,750$ account-period observations from 348,802 beneficiaries. Standard errors are clustered at the bank branch level. Whiskers denote 95% confidence intervals. Black circles indicate results that are significant at the 5% level.

Figure 8: Savings Rate Conditional on Saving (Percent of Income)

Notes: $N = 4,048,978$ account-period observations for 348,774 beneficiaries. The lower number of account-period observations compared to Figure 6 is due to omitting a period to include lagged net balance. This figure shows the savings rate conditional on saving, which we use as an input to estimate the equilibrium buffer stock. It plots Φ_k^* from (5), using coefficients from (4). Standard errors are clustered at the bank branch level. Whiskers denote 95% confidence intervals. Black circles indicate results that are significant at the 5% level.

Figure 9: Balance Checks Over Time

Notes: This figure shows the number of balance checks over time after receiving the card. Panels (a), (b), and (c) use the administrative transactions data and express the number of balance checks relative to the last period in the data for each observation. They plot the π_k coefficients from $Balance\ Checks_{it} = \lambda_i + \sum_{k=0}^4 \pi_k D_{it}^k + \varepsilon_{it}$, where $k = 5$ is omitted. Dashed vertical lines indicate timing of debit card receipt. Periods before receiving the card are not included since it was only possible to check balances at Bansefi branches, and these balance checks are not recorded in our data. Each panel corresponds to a narrower definition of balance checks, where the narrower definitions attempt to rule out balance checks for purposes other than monitoring the bank. Panel (a) includes all balance checks, panel (b) balance checks after the transfer was received and on a different day than a withdrawal, and panel (c) after the first withdrawal occurred in the bimester and on a different day than a withdrawal. These definitions are explained in more detail in Section 7.2.1. $N = 848,664$ account-period observations from 223,788 unique *treated* beneficiaries with cards. Accounts in which cards are received in the last period of our data must be excluded in order to omit a D_{it}^k dummy; we also exclude those who receive the card in the second-to-last period in our data since they only have one additional post-card period. Panel (d) shows how self-reported balance checks (from the Payment Methods Survey) differ based on time with the debit card. It plots the number of balance checks per *bimester* among those who have had a card for less vs. more than the median time, and shows the statistical significance of the difference in means, estimated with equation (3), where * indicates $p < 0.1$, ** $p < 0.05$, and *** $p < 0.01$. $N = 1,617$ households in the survey. Whiskers denote 95% confidence intervals.

Figure 10: Within-Account Relation Between Balance Checks and Savings

Notes: This figure shows the negative within-account correlation between the number of balance checks and savings in the account, using the administrative savings and transactions data. It plots the n_c coefficients from $Savings_{it} = \lambda_i + \sum_{c \neq 0} \eta_c \mathbb{I}(Checks_{it} = c) + \varepsilon_{it}$, where savings are expressed in pesos, balance checks are top-coded at 5, and $c = 0$ is the omitted number of balance checks. Each panel corresponds to a narrower definition of balance checks, where the narrower definitions attempt to rule out balance checks for purposes other than monitoring the bank. Panel (a) includes all balance checks, panel (b) balance checks after the transfer was received and on a different day than a withdrawal, and panel (c) after the first withdrawal occurred in the bimester and on a different day than a withdrawal. Whiskers denote 95% confidence intervals. Black circles indicate results that are significant at the 5% level, gray circles at the 10% level, and hollow circles statistically insignificant from 0. $N = 577,295$ account-bimester observations from 139,205 *treated* beneficiaries who began saving at some point after receiving a debit card.

Figure 11: Self-Reported Reasons for Not Saving in Bansefi Account

Notes: This figure compares reasons for not saving in the Bansefi bank account among Oportunidades beneficiaries who have had a debit card for less than vs. more than the median time. It compares the proportion of respondents in each group who have provide the corresponding reason for not saving in response to the questions “Do you leave part of the monetary support from Oportunidades in your bank account?” and if not, “Why don’t you keep part of the monetary support from Oportunidades in your Bansefi savings account?” Beneficiaries who report saving are coded as 0 for each reason for not saving and still included in the mean proportion measures and regressions. The statistical significance of the difference in means is estimated with (3) and displayed at the top of the figure, where * indicates $p < 0.1$, ** $p < 0.05$, and *** $p < 0.01$. Whiskers denote 95% confidence intervals. $N = 1,694$ beneficiaries.

Appendix A Comparison with Other Studies (For Online Publication)

The savings rates in Figure 1 are drawn from papers which meet the following five criteria.

1. We try to include all studies measuring the impact of savings interventions on the stock of savings. This includes offering accounts or other savings devices, deposit collection, financial education, and savings group interventions, as well as sending reminders, changing the interest rate, and defaulting payments. We exclude studies which measure the impact of income shocks and cash transfers on savings, since these are not savings interventions.
2. We only include studies with a duration of at least 6 months.
3. We focus on interventions aimed at adults.
4. Finally, to estimate the savings rate we need to divide the change in savings by total household income. We therefore only include studies that include average household income in their tables, or a household income variable in the replication data. We exclude studies that only provide labor income of the respondent rather than total household income.
5. We include papers published or accepted for publication in peer-reviewed journals, NBER working papers, and other working papers listed as “revise and resubmit” on authors’ websites as of July 2017. This filter intends to avoid using preliminary results.

Most papers report the impact of savings interventions on the stock of savings (i.e., savings balances), which we divide by annual household income. We use intent-to-treat estimates. In the cases that replication data are available, we use the replication data to replicate the studies’ findings and compute the intent-to-treat impact of the intervention on the savings rate. When possible, we use total savings; when this is not available, we use savings in the savings intervention being studied (e.g., in the bank). This appendix provides more detail on how the savings effects in Figure 1 were computed for each study. We also provide details about some studies that were excluded because they did not meet all of the above criteria.

Ashraf, Karlan, and Yin (2006). This study looks at the effect of a deposit collection service in the Philippines. The authors find an effect of the deposit collection service on bank savings after 12 months that is statistically significant at the 10% level, but that dissipates and is no longer significant after 32 months; the effect on total savings after 12 months is of similar magnitude to that of bank savings, but is noisier and not statistically significant. We use the effect on bank savings after 32 months (since the effect on total savings after 32 months is not available). The effect on bank savings after 32 months is 163.52 pesos (Table 6), which we divide by annual household income (129,800 pesos; Table 1, column 2 of the December 2005 version but not included in the final version).

Beaman, Karlan, and Thuysbaert (2014). This study looks at the effect of introducing rotating savings and credit association (ROSCA) groups in Mali to new techniques in order to improve their flexibility, namely allowing members to take out loans from the group savings rather than waiting for their turn to take home the whole pot. We exclude this study from the comparison because it does not include a measure of total household income.

Blumenstock, Callen, and Ghani (2017). This study looks at the effect of default savings contributions out of salary payments in Afghanistan. We exclude this study from the comparison because it includes a measure of salary, but not a measure of total household income.

Brune et al. (2016). This study looks at the effect of allowing farmers in Malawi to channel profits from their harvests into formal bank accounts; some farmers are also offered a commitment account. We exclude this study from the comparison because it does not include a measure of total household income.

Callen et al. (2014). This study looks at the effect of offering deposit collection to rural households in Sri Lanka. We exclude this study from the comparison because it measures the effect of the intervention on the *flow* of savings, but not on the stock. (Note that the flow of savings is self-reported and has a minimum of 0 in the replication data, which means that using the estimate on the flow of savings to estimate the stock could be inaccurate if the flow of savings is negative in some accounts during some months.)

Drexler, Fischer, and Schoar (2014). This study looks at the effect of financial literacy training in the Dominican Republic. In the study, neither the standard accounting nor rules of thumb treatment arms have a statistically significant impact on savings. We use the replication microdata to replicate their results from Table 2 of the impact of training on savings; we then estimate the pooled treatment effect. Because the paper and data set do not include total household income, we use microenterprise sales in the denominator (the sample consisted entirely of microentrepreneurs). We calculate average annual sales among the treatment group at endline in the microdata.

Dupas and Robinson (2013). This study looks at the effect of providing different savings tools to ROSCA members in Kenya: a savings box, locked savings box, health savings pot, and health savings account. We used replication data to replicate the results in the paper and estimate a pooled treatment effect for the three interventions in which savings could be directly measured: the savings box, lockbox, and health savings account. We divide the savings effect by average income among the treatment group (which we calculate using the replication data).

Dupas et al. (forthcoming). This study looks at the impact of providing access to formal savings accounts to households in three countries: Chile, Malawi, and Uganda. In Chile, an endline survey was not conducted due to low take-up, so we cannot include results for this country. For Malawi

and Uganda, we use the intent-to-treat impact of treatment on total monetary savings of \$1.39 in Uganda and \$4.98 in Malawi (Table 4, column 7). We divide by the sum of income of the respondent and income of the spouse (to approximate total household income), which is given in footnote 27.

Karlan et al. (2016). This study looks at the effect of text message reminders to save in Bolivia, Peru, and the Philippines. Because the Philippines is the only country for which income data was collected, it is the only country from the study for which we estimate the effect of treatment on the savings rate. We use replication data to estimate the effect of treatment on the level of savings. (The paper uses a log specification, but for consistency with the other studies we use levels; in both cases, the effect is statistically insignificant for the Philippines.) We divide by average annual income of the treatment group (estimated using the replication data).

Karlan et al. (2017). This study looks at the effect of savings groups on financial inclusion, microenterprise outcomes, women's empowerment, and welfare. Using the replication data, we replicate the results in Table S3 on the effect of savings groups on total savings balance, and divide this by endline average annual income for the treatment group (estimated using the replication data).

Karlan and Zinman (2016). This study looks at the effect of increased interest rates offered by a bank in the Philippines. Using the replication data, we replicate the results in Table 3 for the effect in the various treatment arms; the results for both the unconditional high interest rate and commitment "reward" interest rate treatment arms are statistically insignificant from 0. We then estimate the pooled treatment effect, using the variable for savings winsorized at 5% (since this is consistent with the winsorizing we perform in this paper). We divide by average annual income of the treated (estimated using the replication data).

Kast, Meier and Pomeranz (2018). This study looks at the effects of participating in a self-help peer group savings program in Chile. We use the intent-to-treat estimate of self-help peer groups on average monthly balance, 1871 pesos (Table 3, column 7). Although we would prefer to use the effect on ending balance, Figure 3b shows that average monthly balance is similar to ending balance. We use the estimate winsorized at 5% (since this is consistent with the winsorizing we perform in this paper). We divide the savings effect by average number of household members times average per capita household monthly income (Table 1) times 12 months.

Kast and Pomeranz (2014). This study looks at the effects of removing barriers to opening savings accounts for low-income members of a Chilean microfinance institution, with a focus on the impacts on debt. Because of the focus on debt, we estimate the effect of treatment on *net* savings, or savings minus debt. To obtain estimates of the intent-to-treat effect, we multiply the average savings balance of active account users, 18,456 pesos, by the proportion of the treatment

group who are active users (39%) and add the minimum balance of 1000 pesos times the proportion who take up but leave only the minimum balance (14%), all from Table 2. We then subtract the intent-to-treat effect on debt, $-12,931$ pesos. This gives an effect of $18,456 \cdot 0.39 + 1000 \cdot 0.14 - (-12,931) = 20,251.76$ pesos. We divide this by the average number of household members times average per capita household monthly income (Table 1) times 12 months.

Prina (2015). This study looks at the effects of giving female household heads in Nepal access to savings accounts. We use the replication data to estimate the intent-to-treat effect on savings account balances after 55 weeks, the duration of the study. While the paper shows average bank savings among those who take up accounts, to estimate the intent-to-treat effect we take the bank savings variable and recode missing values (assigned to those who do not take up the account or are in the control group) as zero, then regress this variable on a treatment dummy. We divide by average annual income among the treatment group from the endline survey (available in the replication data).

Schaner (2016). This study looks at the effects of offering very high, temporary interest rates in Kenya. We use the effect on bank savings (Table 3, column 2) and divide it by average monthly income of the treatment group (Table 4, column 6) times 12 months.

Seshan and Yang (2014). This study looks at the effects of inviting migrants from India working in Qatar to a motivational workshop that sought to promote better financial habits and joint decision-making with their spouses in India. The intent-to-treat effect on the level of savings comes from Table 3, column 1. We divide this by total monthly household income (constructed by adding the migrant's income and wife's household's income from Table 1, column 3) times 12 months.

Somville and Vandewalle (2018). This study looks at the effects of defaulting payments into an account for rural workers in India. We use the effect of treatment on savings balances 23 weeks after the last payment, or 33 weeks after the beginning of the study (Table 5, column 3). We divide this by average weekly income (given in the text of the 2016 working paper version, p. 20) times 52 weeks.

Suri and Jack (2016). This study looks at the effects of mobile money access in Kenya. The authors find that an increase in the penetration of mobile money agents within 1 kilometer of a household increases their log savings by 0.021 per agent for male-headed households and 0.032 per agent for female-headed households (Table 1). We exclude this study from the comparison because it does not include a measure of total household income.

Appendix B Additional Figures and Tables (For Online Publication)

Figure B.1: Distribution of Timing of Card Receipt in Household Panel Survey

Notes: This figure shows when households in the Household Panel Survey received debit cards relative to the time of the survey, using survey data merged with administrative data on time of switch to debit cards. For the results using the Household Panel Survey, those who received cards prior to the survey are the “treatment” group and those who received cards after the survey are the “control.” Dashed vertical line indicates timing of survey. $N = 2,942$ households.

Figure B.2: Distribution of Months with the Card at Time of Payment Methods Survey

Notes: This figure shows how long ago households had received Bansefi debit cards before being surveyed in the Payment Methods Survey. We use self-reported months with the card from the survey. $N = 1,617$ beneficiaries.

Figure B.3: Distribution of Timing of Card Receipt in Trust Survey

Notes: This figure shows when households in the Trust Survey received debit cards relative to the time of the survey, using survey data merged with administrative data on time of switch to debit cards. Dashed vertical line indicates timing of survey. $N = 1,694$ beneficiaries.

Figure B.4: Number of Withdrawals Over Calendar Time in the Control Group

Notes: This figure shows the number of withdrawals in the control group per bimester over time using the administrative transactions data. Since the control did not receive cards during our study period, the x-axis is in calendar time rather than in time relative to the switch to cards. The shaded area denotes the 95% confidence interval. Standard errors are clustered at the bank branch level. $N = 2,584,375$ account-bimester observations from 93,018 unique *control* beneficiaries.

Figure B.5: Effect of Debit Cards on Savings Rate without Transfer Interactions

Notes: This figure shows the effect of debit cards on the savings rate when $Transfers_{it}$ are not included on the right hand side of (4). Specifically, it plots $(\hat{\alpha}_{k^*} + \hat{\xi}_{k^*} \omega_{k^*-1}) / \bar{Y}$ from $\Delta Savings_{it} = \lambda_i + \delta_t + \sum_{k^*=a}^b \alpha_k D_{it}^k + \theta Savings_{i,t-1} + \sum_{k^*=a}^b \xi_k D_{it}^{k^*} \times Savings_{i,t-1} + \varepsilon_{it}$, where ω_{k^*-1} is average lagged balance k^* periods before starting to save, and \bar{Y} is average income. Whiskers denote 95% confidence intervals, estimated using the delta method. Black circles indicate results that are significant at the 5% level, and hollow circles statistically insignificant from 0. $N = 4,315,970$ account-period observations from 348,802 beneficiaries.

Figure B.6: Savings among Non-Oportunidades Debit Card Account Holders (Pesos)

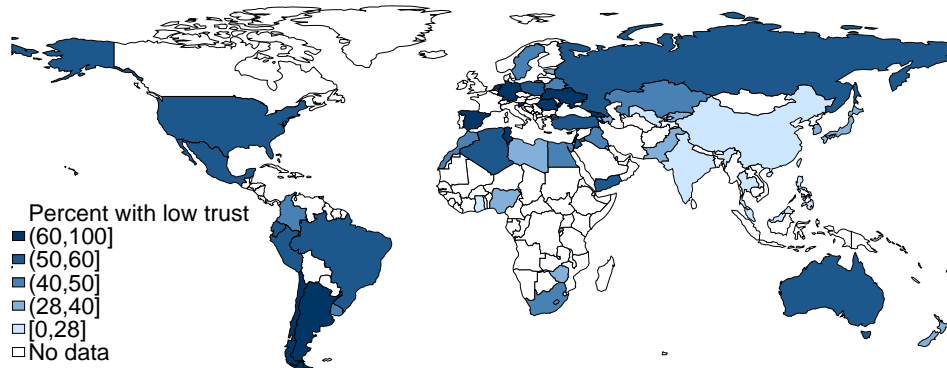

Notes: This figure shows mean savings per four-month period among non-Oportunidades beneficiaries with a debit card who opened accounts in 2007 (in pesos). Savings among non-Oportunidades debit card holders were not increasing over time during the period of our study, which suggests that our results are not driven by a decrease in transaction costs over time. $N = 2721$ non-Oportunidades accounts opened at a sample of 117 Bansefi branches in the year 2007.

Figure B.7: Self-Reported Knowledge of Technology and Fees

Notes: $N = 1,617$ from the Payment Methods Survey. In some regressions if there were respondents who reported “don’t know” or refused to respond N can be smaller. It plots the outcome variable among those who have had a card for less vs. more than the median time, and shows the statistical significance of the difference in means, estimated with equation (3). In Panel (a) outcomes are self-reported transaction fees and in Panel (b) outcomes are self-reported knowledge of how to use the debit card. Standard errors are clustered at the locality level, using pre-treatment (2004) locality. Whiskers denote 95% confidence intervals. None of the differences in means is statistically significant from 0.

Figure B.8: Low Trust in Banks Around the World

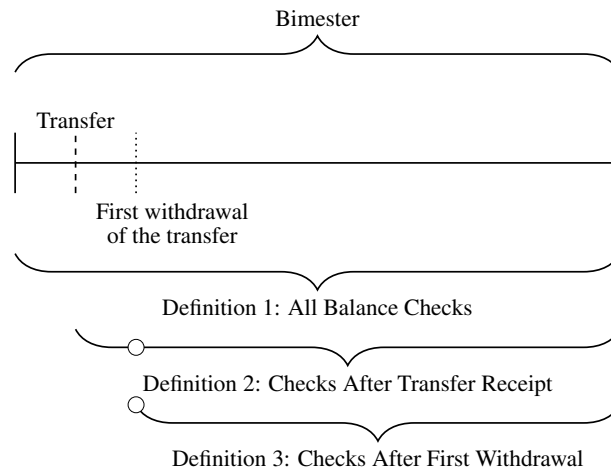

Notes: This figure shows that trust in banks is low across the world. Low trust in banks is defined as “not very much confidence” or “none at all” in response to the following question from the World Values Survey, Wave 6 (2010–2014): “Could you tell me how much confidence you have in banks: a great deal, quite a lot, not very much or none at all?” Darker shades indicate countries with a higher share of the population reporting low trust in banks. $N = 82,587$ individuals in 60 countries.

Figure B.9: Cross-Country Trust in Banks and Saving in Financial Institutions

Notes: This figure shows that internationally, the proportion of adults who save in financial institutions is associated with the proportion that trust banks. The y-axis plots residuals from a regression of the proportion saving financial institutions (from Global Findex) on controls (average age, education, and perceived income decile from the World Values Survey Wave 6, GDP per capita levels and growth from World Development Indicators). The x-axis plots residuals from a regression against the same controls of the proportion that respond “a great deal of confidence” or “quite a lot of confidence” in response to the WVS question “could you tell me how much confidence you have in banks?” The solid line shows a kernel-weighted local polynomial regression, while the gray area is its 95% confidence interval. $N = 56$ countries.

Figure B.10: Stylistic Illustration of Balance Check Definitions

Notes: This figure illustrates the three definitions of balance checks that we use. For illustration we use the scenario where one withdrawal is made during the bimester. The first definition includes all balance checks in the bimester. The second definition includes balance checks that occur after the transfer, not including checks on the same day as a withdrawal (hence the hollow circle in the bracket for definition 2). The third definition includes only balance checks that occur after the first withdrawal of the bimester, when it is not conceivable that the beneficiary could be checking if the transfer has arrived.

Table B.1: Baseline Summary Statistics from Administrative Account Data

	(1) Mean	(2) Standard Deviation	(3) 25th Percentile	(4) Median	(5) 75th Percentile
Number of client deposits	0.01	0.11	0	0	0
Number of withdrawals	1.10	0.29	1	1	1
Made exactly 1 withdrawal	0.90	0.30	1	1	1
Made exactly 2 withdrawals	0.09	0.28	0	0	0
Made 3 or more withdrawals	0.01	0.10	0	0	0
% of transfer withdrawn	99.51	3.24	100	100	100
Size of Oportunidades transfer (pesos)	1539.96	1029.94	470.00	1315.00	2180.00
Net balance (pesos)	123.85	181.49	1.86	41.68	161.62
Years with account	3.49	1.50	2.63	3.43	5.19

Notes: This table shows means and standard deviations for account use summary variables constructed from the transactions-level data, measured at baseline (i.e., before the debit card rollout started). Specifically, data from the first bimester of 2008 is used, so each measure can be interpreted as the average across accounts in a single bimester before the rollout began. Based on data from $N = 268,222$ beneficiary accounts, which is the subset of accounts that existed at the beginning of 2008.

Table B.2: Supply-Side Response

	Total		Bansefi	
	ATMs	Branches	ATMs	Branches
Current quarter	−0.37 (1.51)	−0.01 (0.34)	0.00 (0.00)	−0.01 (0.02)
1 quarter lag	−1.79 (2.49)	0.10 (0.37)	−0.01 (0.01)	0.02 (0.02)
2 quarter lag	2.04 (3.72)	0.12 (0.39)	0.01 (0.01)	0.01 (0.02)
3 quarter lag	−0.57 (1.11)	−0.01 (0.29)	−0.01 (0.01)	0.02 (0.02)
4 quarter lag	2.29 (2.54)	−0.28 (0.64)	0.00 (0.00)	−0.04 (0.03)
5 quarter lag	−1.13 (2.56)	0.08 (0.81)	0.00 (0.00)	0.00 (0.02)
6 quarter lag	−0.31 (3.60)	0.94 (0.67)	0.00 (0.00)	0.02 (0.02)
1 quarter lead	0.66 (1.74)	−0.25 (0.40)	0.00 (0.00)	−0.01 (0.02)
2 quarter lead	3.96 (3.65)	0.11 (0.40)	0.01 (0.01)	0.00 (0.02)
3 quarter lead	−0.06 (4.18)	0.26 (0.65)	−0.01 (0.02)	−0.01 (0.03)
4 quarter lead	−2.50 (4.04)	0.83 (0.78)	0.00 (0.01)	−0.04 (0.05)
5 quarter lead	3.97 (3.19)	0.27 (0.40)	0.00 (0.00)	0.01 (0.02)
6 quarter lead	5.18 (3.03)	−0.98 (0.97)	0.01 (0.01)	−0.04 (0.03)
Mean control group	46.08	37.13	0.09	1.42
F-test of lags	0.59	0.60	0.73	1.15
[p-value]	[0.74]	[0.73]	[0.63]	[0.33]
F-test of leads	0.87	1.00	1.24	0.79
[p-value]	[0.52]	[0.42]	[0.29]	[0.58]
Municipality fixed effects	Yes	Yes	Yes	Yes
Quarter fixed effects	Yes	Yes	Yes	Yes

Notes: This table shows that there was no supply-side response of banking infrastructure to the debit card expansion, using data on ATMs and bank branches by municipality by quarter from CNBV. It also shows that the debit card rollout did not follow a recent expansion of banking infrastructure. Each column is a separate regression with a different dependent variable; the table shows β_k from $y_{mt} = \lambda_m + \delta_t + \sum_{k=-6}^6 \beta_k D_{m,t+k} + \varepsilon_{mt}$. The F-test of lags tests $\beta_{-6} = \dots = \beta_{-1} = 0$; the F-test of leads tests $\beta_1 = \dots = \beta_6 = 0$. $N = 2,491$ municipality-quarter observations from 199 municipalities.

Appendix C Sample of Materials Received by Beneficiaries (For Online Publication)

Figure C.1: Flyer Provided with the Debit Card (Front)

Notes: This flyer is provided by Oportunidades together with the debit card. The front of the flyer provides activation instructions and security tips regarding the PIN number and debit card.

Figure C.2: Flyer Provided with the Debit Card (Back)

L@Red de la Gente
Un mundo que crece para ti

**COMPRA O RETIRO DE EFECTIVO
EN ESTABLECIMIENTO**

Puedes realizar compras en cualquier establecimiento afiliado a VISA ELECTRON.

USO EN CAJERO AUTOMÁTICO

Puedes realizar operaciones en cualquier cajero con logotipos  

1. Introduce o desliza tu Tarjeta de Débito como lo indica el cajero automático. 
2. Teclea tu NIP (Número de Identificación Personal) que te ha sido entregado. 
3. Selecciona la operación que deseas realizar: Retiro, Consulta de Saldo, Cambio de NIP, Venta Genérica (tiempo aire para teléfonos celulares), etc. 
4. Una vez que has realizado la operación, no olvides retirar tu Tarjeta de Débito y el comprobante de la operación realizada. 

1. Al pagar en un establecimiento con Tarjeta de Débito, no la pierdas de vista. 
2. Cuando te entreguen el voucher (comprobante de pago), verifica que la cantidad impresa sea la misma de tu compra. 
3. Firma tu voucher. No permitas que impriman más de un voucher. 
4. Conserva tus vouchers para confirmar las operaciones que has realizado con tu Tarjeta de Débito. 
5. Con tu Tarjeta de Débito puedes retirar efectivo de tu cuenta en Gigante, Comercial Mexicana y WalMart. Entrega tu tarjeta al cajero (a) y solicita la cantidad que deseas retirar. 

Paga con tu tarjeta y gana de Boletazo

Notes: The back of the flyer provides instructions on using the card to withdraw money at ATMs and to make purchases. It clarifies that the card can be used to withdraw money at any ATM within the networks RED and PLUS (which cover almost all ATMs in Mexico) and at major grocery stores.

Figure C.3: Sample Calendar of Transfer Dates Given to Beneficiaries

**Calendario Fijo de Retiro

Consecutivo: 1005

Notes: This is a sample of the calendars that provide the transfer dates to recipients. For each bimester in the following year, it states the corresponding payment date. It reminds recipients that they should use their debit cards after the indicated date at ATMs or establishments accepting VISA. It also reminds them that they are allowed two free transactions per bimester at ATMs.

Appendix D Mechanical Effect (For Online Publication)

This appendix defines the “mechanical effect,” which we use to compute net balances. We explain the logic behind the mechanical effect, present an example, and provide a step by step guide for its computation, summarized in Table D.1.

D.1 Logic of the Mechanical Effect

The mechanical effect is the contribution to average balances from the transit of transfers in recipients’ accounts. Since the mechanical effect does not represent net (long-term) savings, or even saving from one period to the next, our goal is to net it out from average balances and construct a measure of net balances, $Net\ Balance_{it}$. Changes in the mechanical effect can arise due to changes in the *frequency* of withdrawals. For example, if client A begins the period with 0 balance, receives 2,000 pesos in her account, and withdraws 1,000 pesos on the first day of the period, and the other 1,000 pesos midway through the period, her average balance will equal $1,000 * 0 + 1,000 * \frac{1}{2} = 500$ pesos. Compared to client B who withdrew the entire 2,000 pesos on the first day of the period, client A’s average balance is 500 pesos higher, but both end the period with a balance of zero. Their net balances, constructed as average balance minus mechanical effect, are both equal to zero.

Changes in the mechanical effect can also arise from changes in the *timing* of withdrawals, compared to the deposit dates. The deposit date is usually known by the recipients: Oportunidades generally disburses transfers within the first week of the bimester, and the program distributes calendars stating the dates when accounts will be credited. Nevertheless, beneficiaries may not withdraw their benefits on the day they are deposited, which also leads to a mechanical effect that contributes to the average balance. In our data, the mechanical effect can thus change for debit card recipients relative to the control group as a result of increased withdrawal frequency of smaller amounts and changes in time between the deposit and first withdrawal.

Finally, we need to compare not only the timing of deposits and withdrawals, but also their relative sizes. Although the calculation is simple, there are several cases to consider depending on the number of withdrawals, when they occur, and whether they exceed the amount deposited that period. We use an example to exemplify the steps involved.

D.2 Example:

1. Select a pattern where clients received a single deposit (the most common, although as explained previously, beneficiaries receive more than one Oportunidades deposit in some bimesters)
2. Select a pattern with one deposit followed by two withdrawals (DWW)
3. The pattern with one deposit and two withdrawals (DWW), must fit in one of the following three scenarios: (a) the deposit is less than the first withdrawal ($W_1 \geq D$), (b) the deposit is

larger than the first withdrawal but smaller than the sum of the two withdrawals ($W_1 < D$ & $W_1 + W_2 \geq D$), (c) the deposit is larger than the sum of withdrawals ($W_1 + W_2 < D$).

4. Compute the mechanical effect, at the individual level, for each of the three scenarios discussed above:
 - (a) The deposit is less than the first withdrawal \Rightarrow the mechanical effect is just the time lapse between the deposit and the first withdrawal times the deposit amount ($lapse_{DW_1} * D$).
 - (b) The deposit is larger than the first withdrawal but smaller than the sum of the two withdrawals \Rightarrow the mechanical effect is the time lapse between the deposit and the first withdrawal times the amount of the first withdrawal, plus the time lapse between the deposit and the second withdrawal times the remaining deposit amount after subtracting the first withdrawal ($lapse_{DW_1} * W_1 + lapse_{DW_2} * (D - W_1)$).
 - (c) The deposit is larger than the sum of the withdrawals \Rightarrow the mechanical effect is the time lapse between the deposit and the first withdrawal times the amount of the first withdrawal, plus the time lapse between the deposit and the second withdrawal times the amount of the second withdrawal ($lapse_{DW_1} * W_1 + lapse_{DW_2} * (W_2)$).

Table D.1 shows the most common of the cases we considered as well as their prevalence in the data.

D.3 Steps

More generally we follow the steps below:

1. We separate the sample based on the number of transfers received by Oportunidades' beneficiaries: 85% of beneficiary-bimester pairs receive a single transfer in the bimester and 15% received two transfers in the same bimester. See footnote 26 for a description of the reasons some beneficiary-bimester pairs include more than one transfer.
2. We determine the pattern of transactions: for example, a beneficiary who first received a deposit and then performed two withdrawals has a sequence (D, W_1, W_2) , or DWW for short.
3. We compare the size of the deposit to the withdrawals, and generate different scenarios. These scenarios depend on the relative size of the deposit and withdrawals: each withdrawal could be larger than the deposit, their sum might be larger, or the deposit is larger than the sum of withdrawals.

Table D.1: Computation of Mechanical Effect

Pattern	% Total	Conditions	Mechanical Effect
<i>Panel A. Regular patterns: single deposit into account in the bimester</i>			
(1) DW	73.4	$W \leq D$ $W > D$	$\text{lapse}_{DW} * W$ $\text{lapse}_{DW} * D$
(2) DWW	9.1	$W_1 \geq D$ $W_1 < D \text{ \& } W_1 + W_2 \geq D$ $W_1 + W_2 < D$	$\text{lapse}_{DW_1} * D$ $\text{lapse}_{DW_1} * W_1 + \text{lapse}_{DW_2} * (D - W_1)$ $\text{lapse}_{DW_1} * W_1 + \text{lapse}_{DW_2} * (W_2)$
(3) DWWW	1.7	$W_1 \geq D$ $W_1 < D \text{ \& } W_1 + W_2 \geq D$ $W_1 + W_2 < D \text{ \& } W_1 + W_2 + W_3 \geq D$	$\text{lapse}_{DW_1} * D$ $\text{lapse}_{DW_1} * W_1 + \text{lapse}_{DW_2} * (D - W_1)$ $\text{lapse}_{DW_1} * W_1 + \text{lapse}_{DW_2} * W_2$ $+ \text{lapse}_{DW_3} * (D - W_1 - W_2)$
<i>Panel B. Irregular patterns: multiple deposits into account in the bimester</i>			
(4) DDWW	3.1	$W_1 \leq D_1 \text{ \& } W_2 \leq D_2$ $W_1 > D_1 \text{ \& } W_2 \leq D_2$ $W_1 \leq D_1 \text{ \& } W_2 < D_2$ $W_1 > D_1 \text{ \& } W_2 > D_2$	$\text{lapse}_{D_1W_1} * W_1 + \text{lapse}_{D_2W_2} * W_2$ $\text{lapse}_{D_1W_1} * D_1 + \text{lapse}_{D_2W_2} * W_2$ $\text{lapse}_{D_1W_1} * W_1 + \text{lapse}_{D_2W_2} * D_2$ $\text{lapse}_{D_1W_1} * D_1 + \text{lapse}_{D_2W_2} * D_2$
(5) DWD	3.0	$W \leq D_1$ $W > D_1$	$\text{lapse}_{D_1W} * W$ $\text{lapse}_{D_1W} * D_1$
(6) DDW	2.7	$W \geq D_1 + D_2$ $W < D_1 + D_2 \text{ \& } W \leq D_2$ $W < D_2$	$\text{lapse}_{D_1W} * D_1 + \text{lapse}_{D_2W} * D_2$ $\text{lapse}_{D_1W} * (W - D_2) + \text{lapse}_{D_2W} * D_2$ $\text{lapse}_{D_2W} * W$
(7) DWDW	1.6	$W_1 \leq D_1 \text{ \& } W_2 \leq D_2$ $W_1 > D_1 \text{ \& } W_2 \leq D_2$ $W_1 \leq D_1 \text{ \& } W_2 < D_2$ $W_1 > D_1 \text{ \& } W_2 > D_2$	$\text{lapse}_{D_1W_1} * W_1 + \text{lapse}_{D_2W_2} * W_2$ $\text{lapse}_{D_1W_1} * D_1 + \text{lapse}_{D_2W_2} * W_2$ $\text{lapse}_{D_1W_1} * W_1 + \text{lapse}_{D_2W_2} * D_2$ $\text{lapse}_{D_1W_1} * D_1 + \text{lapse}_{D_2W_2} * D_2$

Notes: D_i indicates the i th deposit and W_i indicates the i th withdrawal within a bimester. $\text{lapse}_{D_iW_j}$ measures the number of days between the i th deposit and the j th withdrawal, divided by the number of days in the bimester. The patterns listed here represent 95% of all bimonthly patterns, but all patterns representing at least 0.01% of all account-bimester pair patterns have been coded to obtain an estimate of the mechanical effect.

4. We compute the mechanical effect. To do this, we measure the lapse of time, in days, which passes between the deposit and each withdrawal, and multiply the time lapses by the amount of the transfer which only transited through the account, and was not kept in the account through the end of and into the next bimester.

Appendix E Reasons for Variance in Transfers (For Online Publication)

When there is an election, federal law requires Oportunidades to give the transfer in advance so that there is no payment close to the election month. In practice, this means that beneficiaries receive no payment in the bimester of the election and an additional payment in the preceding bimester. If a family does not comply with program conditions such as school attendance and

health check-ups, the payment is suspended, but if the family returns to complying with the conditions, the missed payment is added into a future payment. Payments also vary systematically by time of year, as the program includes a school component that is not paid during the summer, and a school supplies component that is only paid during one bimester out of the year. Finally, changes in family structure affect the transfer amount because one child might age into or out of the program, for example.
